# The mechanics and design of a lightweight three-dimensional graphene assembly

Zhao Qin,<sup>1\*</sup> Gang Seob Jung,<sup>1\*</sup> Min Jeong Kang,<sup>1</sup> Markus J. Buehler<sup>1,2†</sup>

Recent advances in three-dimensional (3D) graphene assembly have shown how we can make solid porous materials that are lighter than air. It is plausible that these solid materials can be mechanically strong enough for applications under extreme conditions, such as being a substitute for helium in filling up an unpowered flight balloon. However, knowledge of the elastic modulus and strength of the porous graphene assembly as functions of its structure has not been available, preventing evaluation of its feasibility. We combine bottom-up computational modeling with experiments based on 3D-printed models to investigate the mechanics of porous 3D graphene materials, resulting in new designs of carbon materials. Our study reveals that although the 3D graphene assembly has an exceptionally high strength at relatively high density (given the fact that it has a density of 4.6% that of mild steel and is 10 times as strong as mild steel), its mechanical properties decrease with density much faster than those of polymer foams. Our results provide critical densities below which the 3D graphene assembly starts to lose its mechanical advantage over most polymeric cellular materials.

## INTRODUCTION

Graphene is one of the stiffest and strongest materials (1, 2). Besides its outstanding mechanical properties, its atomic thickness and large surface area make it ideal for many engineering applications (3–5), albeit materials-by-design examples of using graphene to form bulk materials and achieve targeted material properties remain rare. A single piece of graphene is too delicate to generate mechanical functions; it is beneficial to have graphene preassembled as a three-dimensional (3D) scaffold, inheriting high stiffness and strength from the 2D graphene as the building block. This assembly by design is applicable to materials science, energy and environmental innovations, and many other fields of study (6–10). There is recent progress in making graphene-based porous materials, and several different experimental methods have been used to produce the material (7, 10, 11). These materials combine lightness with strength, and it is claimed that they can be lighter than air (12). It is intriguing to ask whether the material, in vacuum, can be a substitute for helium in unpowered flight; in this case, the material must be sufficiently strong to avoid being crushed by the surrounding air pressure. Although the mechanical behavior of graphene per se has been well characterized, the relationship between its porous structure and its mechanics is largely unknown, and the experimental measurements for its stiffness and strength vary widely (12–19). Moreover, the failure mechanisms are not well understood, and it is not clear how its mechanical properties relate to its structure from the nanoscale to larger scales. Mechanical models derived from computational modeling and experiments can guide design strategies to improve the mechanical performance of this material. Here, we focus especially on studying the material architecture that allows graphene to form stable 3D porous bulk materials, implemented at different scales in the material, to achieve a set of target bulk material properties including stiffness and tensile and compression strength, which are the mechanical properties most involved with engineering applications.

In the literature, the strength of a 3D graphene assembly has been measured using previous tensile tests (12, 14, 16). A material with a bulk density of 1.5 to 110 mg/cm<sup>3</sup> has been measured to have a tensile strength of 0.011 to 11 MPa (12, 14, 16). Considering that its building block is graphene, which has a density of 2300 mg/cm<sup>3</sup> and a strength of 130 GPa (1), its strength is estimated to be 2.2 to 1360 MPa by using the same scaling laws as the polymeric open-cell foam, because the strength-density plot has a slope of  $3/2$  on a double logarithmic plot (20, 21). This estimation is several orders of magnitude larger than what is measured in previous experiments (12, 14, 16). Such a sharp difference suggests that the mechanics of the 3D graphene assembly are very different from those of conventional polymeric foams.

## RESULTS

### Full atomic models of the 3D graphene assembly

To understand this difference, we built full atomic models of the 3D graphene assembly in molecular dynamics (MD) simulations by mimicking the synthesis of the porous material. Large-scale simulations based on a reactive force field (22–24) are performed to simulate the process of fusing graphene flakes together into the 3D assembly (see fig. S1 and Supplementary Materials). The initial model, as illustrated in Fig. 1A, is composed of graphene flakes with dimensions following the lognormal distribution to avoid negative values for the dimensions and spherical inclusions of a constant diameter that mimic the effect of water clusters in freeze-casting porous graphene materials (13). The graphene flakes have no functional groups, and the edges are modeled without hydrogen for efficient formation of covalent bonds between flakes, which result in a 3D graphene assembly close to the polycrystalline graphene from chemical vapor deposition (CVD) (25, 26). It has been shown that CVD graphene in low hydrogen pressure is not terminated by hydrogen or functional groups (27). These graphene flakes are randomly distributed and oriented inside the simulation box (Fig. 1B). This initial state is close to a gas with a density of 3.9 mg/cm<sup>3</sup>. We design a cyclic protocol to condense the material. Each of the cycles is composed of four stages, and we control both the temperature and pressure for each stage, as shown in Fig. 1C. Repeating the cycle enables us to obtain the condensed graphene flakes, as shown in Fig. 1E. We find that, by repeating the cycle more than eight times, we are able to obtain an

equilibrated structure and the total number of covalent bonds  $N_{\text{C-C}}$  converges from 1.22 to 1.4 for each carbon atom (Fig. 1G), which is close to that of the ideal graphene with an infinitely large size (1.5 per atom). After removing the inclusions and equilibrating the carbon material under ambient conditions, we are able to obtain a stable structure of the 3D graphene assembly that closely represents the irregular experimental sample, as shown in Fig. 1F. It has a density of  $366.2 \text{ mg/cm}^3$ , which is 4.6% that of mild steel. The diameter of the spherical inclusions can be tuned during synthesis to adjust the density and make the material lighter. We note that most of the walls are curved adjacent to the junction where several of them meet (Fig. 1F). This curvature is induced by defects in the form of pentagons and heptagons at grain boundaries (25), which cause out-of-plane deformations (28, 29) and achieve defined 3D architectures composed of nondevelopable surfaces (8).

### Mechanical response of the 3D graphene assembly under loading

We estimate the mechanical properties of this material by simulating uniaxial tension and compressive tests. A series of snapshots of the structure during the simulation is given in Fig. 2A, and the full force extension–compression curve is given in Fig. 2B. The material has a Young's modulus of 2.8 GPa (given by the slope of the stress-strain curve at the zero strain point) and a tensile strength of 2.7 GPa (the peak stress in the stress-strain curve), which is an order of magnitude higher than that of mild steel. We observe that the strain stiffening behavior of

the material in tension is governed by the bending of the graphene walls, aligning them toward the loading direction at large deformations before rupture (Fig. 2A, iii). The compressive strength of the material is measured to be 0.6 GPa, which corresponds to the point before the more significant increment of the stress (measured by averaging the stress between 0.1 and 0.3 strain), and it is found to be governed by the buckling of the walls in compression (Fig. 2A, i). We find that, for small deformations (less than 0.02 strain), Poisson's ratio is measured to be 0.3 in both tensile and compressive loadings (Fig. 2C). For large compressive deformations, there is almost zero strain in directions perpendicular to the loading direction once buckling occurs (Fig. 2C and fig. S2 for volume change). This agrees with what has been observed in recent experiments (8, 30). Note that we did not consider functional groups in the current 3D graphene structures because our model is constructed on the basis of the CVD graphene. Additional chemical groups could be expected to affect both the nonbonded interaction between two facing layers and the material strength of the graphene itself; these effects may play roles that could affect the mechanics of the graphene but are not included in our current model.

### Scaling laws of the mechanics of the 3D graphene assembly

We repeat the mechanical tests in computational simulations but use different material samples with their mass density varying between 80 and  $962 \text{ mg/cm}^3$  by altering the inclusion diameter during the material preparation. We measure the Young's modulus ( $E$ ), tensile strength ( $\sigma_T$ ), and compressive strength ( $\sigma_C$ ) obtained in our simulations (data in table S1),

**Fig. 2. Mechanical tests on the 3D graphene assembly.** (A) Simulation snapshots of the full atomic graphene structure in tension and compressive tests that are taken at  $\varepsilon_x = -0.5, 0.0, 0.6,$  and  $1.0$  for (i) to (iv), respectively. The atomic stress and its distribution at different strain states are computed and included in fig. S3. The symmetric distribution of positive and negative stress suggests that the graphene is largely bent under deformation. Insets show schematics for the different mechanisms of the material behavior under compression and tension. (B) Full stress-strain curve of the material under compression and tension force. (C) The average strains in the two directions other than the loading direction as a function of  $\varepsilon_x$ ; for  $|\varepsilon_x| < 0.02$ , the slope of the curve is measured to be  $-0.3$ . For larger deformations, the three linear fits on the plot have slopes of  $0.03, -0.6,$  and  $0.04$  from left to right of the curve.

and we normalize these results by the mechanical features of graphene ( $\rho_s, E_s,$  and  $\sigma_{Ts}$ ), as summarized in Fig. 3. In analogy to the mechanics of polymeric open-cell foam (20, 21), we plot the data points as functions of the material density on double logarithmic graphs, which allow us to determine the scaling laws of the mechanical properties of the material as

$$\frac{E}{E_s} = \left( \frac{\rho}{\rho_s} \right)^{2.73 \pm 0.09} \quad (1)$$

$$\frac{\sigma_T}{\sigma_{Ts}} = \left( \frac{\rho}{\rho_s} \right)^{2.01 \pm 0.05} \quad (2)$$

$$\frac{\sigma_C}{E_s} = \left( \frac{\rho}{\rho_s} \right)^{3.01 \pm 0.01} \quad (3)$$

Compared to previous experiments on 3D graphene assembly (the so-called graphene aerogel) in the literature, our results show an overall agreement with the results obtained from different measurements (12–19). They follow the same scaling law, suggesting that their mechanics as a function of the density are mainly dominated by their structures, and our simulation model captures the essential mechanism of their deformation under mechanical loading up to failure. However, we note that the experiments described in the literature use several different techniques to prepare the

material samples, such as CVD and freeze-drying (7, 11, 19), leading to different defect forms, and thereby, the results are more dispersed than our modeling results. Considering the power index of the functions of mechanics versus density, Young's modulus ( $2.73 \pm 0.09$ ), tensile strength ( $2.01 \pm 0.05$ ), and compressive strength ( $3.01 \pm 0.01$ ) are overall larger than those of conventional polymeric open-cell foams (2, 1.5, and 2 for Young's modulus, tensile strength, and compressive elastic strength, respectively) (20, 31), suggesting that the microstructures of the graphene assembly are very different from those of conventional polymeric open-cell foams. From conventional polymeric foams, it has been learned that a bending-dominated foam structure generally gives a larger power index than a stretch-dominated foam structure (21). This point is supported by the distribution of atomic stress in our simulations, which shows that the stress distribution is quite symmetric for atoms under compression (negative stress) and tension (positive stress), as shown in fig. S3. Therefore, the results suggest that the high power indexes of the 3D graphene assembly are caused by the bending-dominated behavior that may be even stronger than the ideal bending-dominated polymeric open-cell foams. Our findings would be applicable to predicting the overall mechanical properties of graphene aerogels. It can be further used not only to decide the aerogel density according to the specific mechanical requests but also to provide a well-defined trade-off between density and mechanics. This knowledge will be useful for designing complex structures and composite materials by assigning materials with an optimized material distribution that leads to the highest mechanical strength with the least total material usage.

**Fig. 3.** The normalized Young's modulus (A), tensile strength (B), and compressive strength (C) of the 3D graphene assembly as a function of its mass density. The data points include mechanical test results of the full atomic 3D graphene assembly (PG), the full atomic gyroid graphene (GG), and the 3D-printed polymer samples (3D-printed). The solid curves are plotted according to scaling laws obtained in the study with slopes of 2.73, 2.01, and 3.01 for (A), (B), and (C), respectively.  $\rho_s = 2300 \text{ mg/cm}^3$ ,  $E_s = 1.02 \text{ TPa}$ , and  $\sigma_{Ts} = 130 \text{ GPa}$  correspond to the density, Young's modulus, and tensile strength of graphene for its in-plane mechanics, which are used to normalize the properties of graphene materials (PG, GG, and references mentioned).  $\rho_s = 1175 \text{ mg/cm}^3$ ,  $E_s = 2.45 \text{ GPa}$ , and  $\sigma_{Ts} = 50 \text{ MPa}$  correspond to the density, Young's modulus, and tensile strength of the bulk material properties of polymer material for 3D printing, which are used to normalize the results of 3D-printed samples.

### Mechanics of a pristine gyroid graphene structure

To understand the effect of defects, we built an idealized atomic 3D graphene structure by taking its geometry as a periodic gyroid porous structure, which accounts for the common geometric feature of the graphene structure because each unit cell is composed of a highly curved 2D graphene surface (20, 21, 31). The gyroid shape guarantees minimum density under a given periodicity because the structure is known to have a minimum surface area in a given volume (that is, minimal surface), which corresponds to the 2D nature of graphene in 3D geometry. We obtain equilibrated structures by three different processes (see Supplementary Materials and fig. S4), adopting external potential as

$$E_{\text{graphene}} = \sum E_{C-C} + \lambda \sum \left[ \sin\left(2\pi \frac{x_i}{L}\right) \cos\left(2\pi \frac{y_i}{L}\right) + \sin\left(2\pi \frac{y_i}{L}\right) \cos\left(2\pi \frac{z_i}{L}\right) + \sin\left(2\pi \frac{z_i}{L}\right) \cos\left(2\pi \frac{x_i}{L}\right) \right]^2 \quad (4)$$

where  $\sum E_{C-C}$  accounts for all interactions among carbon atoms in graphene, described by the adaptive intermolecular reactive empirical bond order (AIREBO) potential (23, 24);  $\lambda$  is a Lagrange multiplier for the constraint energy of the desired geometry;  $(x_i, y_i, z_i)$  is the Cartesian coordinate of each carbon atom; and  $L$  is the length constant of the periodic structure in all three directions, which directly affects the density of the graphene material as  $\rho \sim L^{-3}$  (see table S2 for detailed data). As the result of iterative modifications of the geometry based on our algorithm, all carbon atoms have a bond number of three, which is the same number as the pristine graphene, with mainly heptagon and pentagon defects to foam curved surfaces. Their coordinates satisfy the minimum  $E_{\text{graphene}}$  and thus, the overall geometry approximates the mathematical form of the gyroid structure as

$$\sin\left(2\pi \frac{x_i}{L}\right) \cos\left(2\pi \frac{y_i}{L}\right) + \sin\left(2\pi \frac{y_i}{L}\right) \cos\left(2\pi \frac{z_i}{L}\right) + \sin\left(2\pi \frac{z_i}{L}\right) \cos\left(2\pi \frac{x_i}{L}\right) = 0 \quad (5)$$

which has the geometry shown in Fig. 4A. On the basis of our new algorithm, we can design and build the atomic structures of the 3D graphene structure with different length constants ( $L$ ), as shown in Fig. 4B. Notably, we ensure the convergence of the coordinate number and potential energy before deciding the final structures, and thus, the lattice structure is overall continuous without large holes, and all carbon atoms mainly have a pentagon, hexagon, or heptagon ring shape, which has been proven to not affect the fracture toughness of graphene (25). We investigate the mechanical properties of gyroid graphene structures by applying tensile and compression deformation to the atomic models and by recording the stress in the material (see the Supplementary Materials for the loading conditions and measurement of mechanical properties; see fig. S5 for the stress-strain curves of the loading tests). Their deformation and failure mechanisms largely represent those of the 3D graphene assembly (fig. S6), and their mechanical properties, including Young's modulus and tensile and compression strength as a function of their material density, are summarized in Fig. 3 (and data in table S2).

### Mechanics of large-scale 3D-printed gyroid structures

We use Eq. 5 to build large-scale 3D gyroid models by using a high-resolution 3D printer (see Materials and Methods for the detailed protocols). Using different combinations of cell size and wall thickness, we are able to design different 3D porous computational models with a gyroid architecture and with material densities ranging from 92.2 to 401.6  $\text{mg/cm}^3$ . The models, as shown in Fig. 4C, provide us samples that are  $10^7$  times longer than the full atomic models of the same gyroid geometry to carry out tensile and compressive tests (Fig. 4, D and E, with strain-stress curves in fig. S7 and detailed snapshots in fig. S8). Material failure, including crack generation and propagation in tensile loading as well as wall buckling and breaking in compressive loading, is also observed in our full atomic simulations. After normalizing the results with the bulk material properties of the 3D printing material (with the numerical value of all the data points summarized in table S3), they agree with the scaling laws as identified for the 3D graphene assembly, as shown in Fig. 3. This agreement suggests that the mechanics of the 3D graphene assembly are mainly governed by its geometry, and the

gyroid structure represents a very relevant architecture. Such an agreement between 3D graphene and 3D-printed models, which are made of photoreactive polymers with mechanics very different from those of graphene, suggests that the index of the scaling laws derived from this study may still be applicable to a wide range of other 2D materials as long as they can turn into gyroid structures similar to graphene.

## DISCUSSION

3D carbon materials of desired mechanical properties by design are useful for multifunctional engineering applications. Our results reveal that, by designing the chemical synthesizing process, especially the reacting conditions, including pressure and temperature, we can fuse graphene flakes and produce stable 3D porous bulk materials with material architecture and density under control. By fully characterizing the material properties, we can derive scaling laws, which can be used to achieve a set of target bulk material properties. We have demonstrated that the scaling laws derived from the 3D graphene assembly can be used to design and predict the mechanical properties of a pristine 3D graphene structure as well as 3D-printed models with gyroid geometries and a wide density distribution, showing that the material architecture features, instead of the mechanics of its constituting materials, play a more dominant role in governing the scaling laws. As shown in the scaling law, higher density provides better mechanics. Also, the connectivity between flakes is critical for the mechanical properties. As shown in the construction of the 3D graphene assembly, refining the structure based on annealing may improve its mechanical properties. The study provides a simple way to predict the mechanics of graphene aerogels, and using graphene aerogels of different densities as building blocks can be helpful in designing larger-scale structures. This conclusion can be generally applied to guide designs of structural materials of diverse functions by using universal constituting materials.

With the scaling law, we can directly answer the question asked earlier: Can we use graphene as a building block to form a 3D bulk

material that is strong yet lighter than air? In particular, can this material be designed and synthesized as a substitute for helium in unpowered flight balloons? This requires the material to satisfy  $\sigma_C > 1$  atm and  $\rho < 1.16$  mg/cm<sup>3</sup> simultaneously. According to the scaling law, these two conditions cannot be satisfied simultaneously because  $\sigma_C > 1$  atm yields  $\rho > 28.7$  mg/cm<sup>3</sup> and  $\rho < 1.16$  mg/cm<sup>3</sup> yields  $\sigma_C < 6.39 \times 10^{-5}$  atm, suggesting either filling gas with a lower density or implementing structural materials as necessary conditions for these applications.

We compare the scaling laws for a 3D graphene assembly with those for other porous polymeric materials. The mechanics-density trade-off for a 3D graphene assembly is significantly more biased than that for conventional porous materials, resulting in a much softer and weaker material once the density of the material decreases (20, 21). For example, although graphene has the highest in-plane stiffness and strength, the advantage of the 3D graphene assembly (particularly its stiffness) over woven structures made of polystyrene may only exist for  $\rho > 10$  mg/cm<sup>3</sup> but not for materials lighter than this critical value, as shown in Fig. 5.

Although the porous graphene assembly can likely (but not directly) substitute helium, its material features, including its ultralight nature, outstanding mechanical properties, high surface area, and stable chemical and thermal properties, remain promising for many engineering applications, making products lighter and stronger, which can thereby play a profound game-changing role in broad industrial areas. Using the knowledge learned from the current study that the natural curved 2D surface of graphene is disadvantageous to the mechanics of the 3D assembly, we are working toward further designing and optimizing the structure of these porous materials by tuning the surface chemistry of graphene and combining the 2D material with other polymers for a more efficient use of the material and to derive improved mechanical scaling laws. The combination of a theoretical model and computational simulations provides a powerful tool to explore these opportunities for carbon material designs.

**Fig. 5. Comparison between the mechanics of the 3D graphene assembly and a polymeric foam as functions of mass density.** Young's modulus (A) and tensile strength (B) of the 3D graphene assembly compared to those of porous polystyrene with a woven and foam structure with  $\rho_s = 1065 \text{ mg/cm}^3$ ,  $E_s = 3.67 \text{ GPa}$ , and  $\sigma_{T5} = 100 \text{ MPa}$ ; its scaling laws,  $\frac{E}{E_s} = \left(\frac{\rho}{\rho_s}\right)^2$  and  $\frac{\sigma_t}{\sigma_{T5}} = \left(\frac{\rho}{\rho_s}\right)^{1.5}$ , were obtained from previous studies (20, 21).

## MATERIALS AND METHODS

### MD simulation and the force field

MD simulations in this study were performed via LAMMPS MD package (22) using the AIREBO force field to model the internal interactions among carbon atoms in graphene (23, 24). This has been widely used and has been proven to be a reliable force field to reproduce the mechanical behavior observed experimentally in graphene (32, 33). According to this model, the total potential energy of the system is given by

$$E = E_{C-C} + E_{C\_inc} + E_{inc\_inc} \quad (6)$$

where

$$E_{C-C} = \frac{1}{2} \sum_i \sum_{j \neq i} \left[ E_{ij}^{\text{REBO}} + \sum_{k \neq i} \sum_{l \neq i, j, k} E_{ijkl}^{\text{TORSSION}} \right] \quad (7)$$

accounts for all interactions among carbon atoms in graphene. Moreover,  $E_{ij}^{\text{REBO}}$  denotes the REBO term of hydrocarbon (24) and  $E_{ijkl}^{\text{TORSSION}}$  is an explicit four-body potential that describes various dihedral angle preferences in hydrocarbon configurations. Detailed expressions for  $E_{ij}^{\text{REBO}}$  and  $E_{ijkl}^{\text{TORSSION}}$  are given in the study of Stuart *et al.* (23).

$$E_{C\_inc} = E_{inc\_inc} = \sum_i \sum_{j \neq i} 4\epsilon \left[ \left( \frac{\sigma}{r_{ij}} \right)^{12} - \left( \frac{\sigma}{r_{ij}} \right)^6 \right] \Xi \quad (8)$$

is the pair interaction between a carbon atom and inclusion particles, as well as the interaction between two inclusion particles, where  $r_{ij}$  is the distance between the two particles (the cutoff function  $\Xi = 1$  for  $r_{ij} < 20 \text{ \AA}$  and  $\Xi = 0$  for  $r_{ij} \geq 20 \text{ \AA}$ ),  $\epsilon = 15 \text{ kcal/mol}$  (which relates to the stiffness of the inclusion), and  $\sigma$  is the zero energy distance with  $r_{ij} = 2^{1/6} \sigma = d/2$  as the effective radius of the inclusion. We found that  $\sigma$  affected the density of the 3D graphene assembly because  $\sigma = 20 \text{ \AA}$  resulted in  $\rho = 80 \text{ mg/cm}^3$ ,  $\sigma = 15 \text{ \AA}$  resulted in  $\rho = 148 \text{ mg/cm}^3$ ,  $\sigma = 10 \text{ \AA}$  resulted in  $\rho = 366.2 \text{ mg/cm}^3$ , and  $\sigma = 2 \text{ \AA}$  resulted in  $\rho = 962 \text{ mg/cm}^3$ .

### Design and modeling of the chemical process of fusing graphene flakes into the 3D graphene assembly

The initial system was composed of 500 rectangular graphene flakes with a dimension of  $L(i)$  for each flake, as well as 500 spheri-

cal inclusions with a uniform diameter  $d$ , as shown in Fig. 1B. The value of  $L$  follows the lognormal distribution with a probability density function of

$$p(L) = \frac{1}{L\sigma_L\sqrt{2\pi}} e^{-\frac{(\ln(L)-\mu)^2}{2\sigma_L^2}} \quad (9)$$

where  $\sigma_L = \sqrt{\ln\left(\frac{L_{SD}}{\bar{L}} + 1\right)}$  and  $\mu = \ln(\bar{L}) - \sigma_L^2/2$  are functions related to the mean value  $\bar{L} = 12 \text{ \AA}$  and the standard deviation  $L_{SD} = 4.8 \text{ \AA}$  used throughout our study. Using the system, we simulated the chemical process of fusing the graphene flakes to form the 3D graphene assembly (details are provided in the Supplementary Materials).

### Tensile test on the 3D graphene assembly

We deformed the 3D graphene assembly in a quasi-static manner. Periodic conditions were applied to all the directions of the simulation box. We first equilibrated the system in the NPT ensemble under ambient conditions ( $T = 300 \text{ K}$  and  $p = 1 \text{ atm}$ ) and then deformed the simulation box in a stepwise fashion for 1% uniaxial strain with  $p = 1 \text{ atm}$  applied to the other two directions. Each strain increment is followed by energy minimization and equilibration in the NVT ensemble with  $T = 300 \text{ K}$ .

### Design and modeling of the pristine periodic gyroid graphene structures

To understand the mechanical properties of the idealized 3D graphene, we used the gyroid structure (following Eq. 5) that has a minimum surface area in a given volume (also called minimal surface). Thus, the shape guarantees the minimum density under a given periodicity. To achieve the geometry, we first introduced the external potential to the Lennard-Jones (LJ) particle system

$$E_{\text{effect}} = \sum E_{LJ} + \lambda \sum \left[ \sin\left(\frac{2\pi}{L}x\right) \cos\left(\frac{2\pi}{L}y\right) + \sin\left(\frac{2\pi}{L}y\right) \cos\left(\frac{2\pi}{L}z\right) + \sin\left(\frac{2\pi}{L}z\right) \cos\left(\frac{2\pi}{L}x\right) \right]^2 \quad (10)$$

to build a triangular template for the initial geometry. It was found that the shorter equilibrium distance of the LJ potential  $E_{LJ} = 4\epsilon \left[ \left( \frac{\sigma}{r_{ij}} \right)^{12} - \left( \frac{\sigma}{r_{ij}} \right)^6 \right]$  than the graphene bond ( $\sim 1.42 \text{ \AA}$ ) was better for the latter process to refine geometry, and  $\epsilon$  had little effect on the geometry if strength of the external potential  $\lambda$  was strong enough to bind atoms on the surface. In our model, the parameters were set to  $\epsilon = 0.25 \text{ kcal/mol}$ ,  $\sigma = 1.15 \text{ \AA}$ ,  $r_{\text{cut}} = 3.0 \text{ \AA}$ , and  $\lambda = 460 \text{ kcal/mol}$ . The initial geometry of LJ particles was chosen as a face-centered cubic (fcc) solid with a  $5.8 \text{ \AA}$  lattice constant, as shown in Fig. 4A (left). Then, the system was heated up to 1000 from 350 K for 100 ps. After the system was cooled down to 10 K for another 100 ps, we obtained the initial triangular geometry of the gyroid, as shown in Fig. 4A (middle) and fig. S3 (B and C). Next, we removed atoms based on the bond number for hexagonal geometry because the triangular geometry was not applicable for the refining algorithm. After obtaining the bond number of all atoms based on the distance criteria (set at  $2 \text{ \AA}$  here), the atoms having more than six bonds were removed. We removed all atoms under these conditions until there was no atom having six bonds. After removing atoms having four and five bonds, we obtained the hexagonal geometry for the next process, as shown in fig. S3E. Finally, we extended the previous algorithm to generate polycrystalline graphene to refine the geometry obtained from previous processes (25). We added atoms based on the bond number and relaxed the structure with energy minimization and short MD runs. We used the modified potential based on Eq. 4 for gyroid graphene with the same parameters for the LJ potential. After removing atoms not satisfying three bonds, we added atoms to make hexagonal structures. Iteratively, this process was repeated until there was no more update. We were able to obtain the final geometry of the gyroid graphene structure, as shown in Fig. 4A (right). The quality of grain boundary was similar to the previous polycrystalline graphene models, most of which had five to seven rings and a few of which had eight rings for the small defects.

### 3D printing of a porous structure with gyroid geometry

A collection of coordinates  $(x, y, z)$  of randomly generated dispersed points on the gyroid surface was generated according to Eq. 5. The total surface area of a unit cell was given by  $S = 2.96L^2$ . MeshLab was used to read the coordinate as input and generate a meshed surface and then extrude to a 3D solid structure with a defined wall thickness  $d$ . The density of the 3D-printed porous material was given by

$$\rho_{3\text{D printed}} = 2.96d\rho_s/L \quad (11)$$

where  $\rho_s$  is the density of the bulk material for printing. Using different combinations of  $d$  and  $L$ , we were able to design different 3D porous computational models with a gyroid architecture and with material densities ranging from  $92.2$  to  $401.6 \text{ mg/cm}^3$ . Thereafter, the computational model was input to a high-resolution and multimaterial 3D printer, Object500, made by Stratasys, which allowed us to print complex geometries at  $20\text{-}\mu\text{m}$  resolution. The material we used for printing is called VeroMagenta, and has  $\rho_s = 1175 \text{ mg/cm}^3$ ,  $E_s = 2.45 \text{ GPa}$ , and  $\sigma_{T_s} = 50 \text{ MPa}$ , corresponding to the density, Young's modulus, and tensile strength of the bulk material properties. The material samples we designed and created for this study, with dimensions of  $1.5 \text{ inches} \times 1.5 \text{ inches} \times 1.5 \text{ inches}$  or  $1.0 \text{ inch} \times 1.0 \text{ inch} \times 1.0 \text{ inch}$  and of various thickness values, are shown in Fig. 4C. Their mechanical properties, which are summarized in table S3, also have a wide range; for example, the Young's modulus of the porous material ranged from  $3.0$  to  $184.9 \text{ MPa}$ .

### Mechanical tests on 3D-printed gyroid samples

The tensile tests were carried out at room temperature with a standard tensile testing machine (MTS Corporation). In each of the tensile tests, the material sample was attached to two T-shaped aluminum substrates with epoxy glue. The aluminum substrates were fixed to the crosshead, which moved at a constant rate of displacement ( $0.01 \text{ mm/s}$ ). For the compressive test, the samples were directly compressed by two parallel crossheads with a large enough flat surface. The upper crosshead was held by a force transducer where the reaction force was measured. The crosshead displacement was measured using a linear voltage displacement transducer mounted inside the actuator. The total force and displacement of the substrate were scanned with  $1 \text{ Hz}$  and saved to the connected data collector. We checked during the multiple tests to ensure that there was no detachment or misalignment of the samples or substrates that could affect the results.
