The timing and nature of igneous activity recorded at a single Mars ejection site can be determined from the isotope analyses of Martian meteorites. Northwest Africa (NWA) 7635 has an Sm-Nd crystallization age of 2.403 ± 0.140 billion years, and isotope data indicate that it is derived from an incompatible trace element–depleted mantle source similar to that which produced a geochemically distinct group of 327- to 574-million-year-old “depleted” shergottites. Cosmogenic nuclide data demonstrate that NWA 7635 was ejected from Mars 1.1 million years ago (Ma), as were at least 10 other depleted shergottites. The shared ejection age is consistent with a common ejection site for these meteorites. The spatial association of 327- to 2403-Ma depleted shergottites indicates >2 billion years of magmatism from a long-lived and geochemically distinct volcanic center near the ejection site.

**INTRODUCTION**

Insights into the duration of igneous activity and the nature of magma sources in Mars are made from analyses of shergottite meteorites—mafic to ultramafic igneous rocks from Mars’ crust composed mainly of pyroxene, plagioclase (commonly maskelynite), and, in many cases, olivine [for example, McSween and Treiman (1)]. Shergottites are also characterized by their trace element concentrations and the radiogenic isotope compositions of their mantle sources [for example, Borg and Draper (2)], which are distinct from those that produced the other Martian igneous rocks classified as nakhlites and chassignites (3). The shergottites were launched from Mars’ crust by large bolide impacts (4, 5); however, the unknown spatial associations of these meteorites before launch and a relatively narrow range of crystallization ages from 150 to 574 million years (My) (6–8) have limited our understanding of long-term igneous processes.

Geochemical data obtained from Northwest Africa (NWA) 7635, a 195.8-g partly fusion-crusted olivine-plagioclase-phryic rock that was found in Algeria in 2012, both extend the recognized period of shergottite magmatism and provide constraints on the prelaunch spatial association of a suite of geochemically related shergottite specimens. This specimen is porphyritic with phenocrysts (up to 200 μm) of plagioclase completely converted to maskelynite, Fe-rich olivine, augite, and low-Ti magnetite in a finer-grained matrix composed mainly of igneous-zoned, Fe-rich augite (see Fig. 1 and the Supplementary Materials). Accessory pyrrhotite and rare ilmenite are present, but no identifiable phosphate grains have been found. Although NWA 7635 does not contain pigeonite, we consider it to be a petrologic variant of a typical shergottite, in much the same way the petrologic variants of the type specimen Shergotty (9, 10) have been included in the shergottite group. Shock features include the presence of maskelynite and glassy veins that crosscut the igneous texture, but there is no evidence for shock-induced reequilibration of igneous textures and compositional zoning. Furthermore, there is no evidence for terrestrial desert weathering products in the sample aliquot analyzed in this study. Isotope analyses of Sm-Nd, Lu-Hf, and Rb-Sr that constrain the age and mantle source compositions were conducted on a 2.2-g portion from the interior of NWA 7635 (table S1). Cosmogenic nuclide concentrations of 10Be (half-life, 1.36 My) and 26Al (half-life, 0.705 My) were measured to constrain the cosmic-ray exposure age, and 14C (half-life, 5730 years) was measured to constrain the terrestrial age; the sum of exposure and terrestrial ages is the time since the launch from the surface of Mars (ejection age).

**RESULTS**

A 143Sm-143Nd isochron age of 2403 ± 140 million years ago (Ma) (2e) was determined from seven mineral and leachate measurements (see Fig. 2, table S2, and the Supplementary Materials for details). This early Amazonian age is about 1.8 billion years older than that of any other recognized shergottite, whose ages fall into the middle- to late-Amazonian epoch in Mars’ geologic history. The mantle source isotope compositions for NWA 7635 were calculated from initial Nd, Hf, and Sr isotope compositions of samples F1 and F5-R (table S3). The calculated initial ε143Nd(CHUR), ε176Hf(CHUR), and 87Sr/86Sr are +29.3 ± 3.1, +39.5 ± 7.8, and 0.699901 ± 0.000025, respectively (all

**Fig. 1.** False-color x-ray compositional map showing the mineralogy and mineral textures of NWA 7635. Mineral labels: O, olivine; P, plagioclase (maskelynite); C, clinopyroxene (augite). Chemical compositions: Fe (purple), Mg (green), Ca (blue), Ti (magenta), and S (yellow). Purple colors in the mesostasis represent Fe-rich augite.
three hydrogen fluoride (HF) uncertainties and scatter in ε units of individual points that define the isochron. As one measurement of whole-rock residue (see the Supplementary Materials), uncertainties are at the 95% confidence level; see the Supplementary Materials). On the basis of these values, as well as (i) a two-stage mineral evolution model (2), (ii) a source formation age of 4504 Ma (11), (iii) a chondritic bulk Mars, and (iv) a Mars formation age of 4567 Ma, the $^{143}\text{Sm}/^{144}\text{Nd}$, $^{176}\text{Lu}/^{177}\text{Hf}$, and $^{87}\text{Rb}/^{86}\text{Sr}$ ratios of the hybridized source are $0.3035 \pm 0.0052$, $0.0629 \pm 0.0035$, and $0.0217 \pm 0.0019$, respectively (Fig. 3). These ratios indicate that NWA 7635 is derived from the most incompatible trace element (ITE)-depleted source yet measured for any Martian rock.

**DISCUSSION**

Source Sm/Nd and Lu/Hf ratios for shergottites (Fig. 3A) [and, for orthopyroxenite Allan Hills 84001 (ALH 84001), see Lapen et al. (12)] show an array that can be interpreted as a three-component mixing relationship between ITE-depleted deep mantle, ITE-depleted shallow mantle, and ITE-enriched shallow upper mantle end-member compositions calculated by Debaille et al. (13). The source compositional range for shergottites can be explained by mixing these three distinct end-members that are hypothesized to have formed during differentiation of a Mars magma ocean (2, 13). A plot of source Rb/Sr versus Sm/Nd ratios of shergottites (inset of Fig. 3A) does not show the three-component mixing relationships because the Rb/Sr and Sm/Nd ratios of the two ITE-depleted end-members are nearly identical.

The mantle source connections between other shergottites and NWA 7635 are further evaluated with the short-lived $^{146}\text{Sm}-^{142}\text{Nd}$ isotope system, a monitor of mantle source reservoirs in Mars that formed in the first 100 to 200 My after planet formation (3). An average of measured $^{142}\text{Nd}/^{144}\text{Nd}$ ratios from each aliquot measured (see the Supplementary Materials) yields $\epsilon^{142}\text{Nd} = 0.918 \pm 0.077$. When compared to other shergottites on a $\epsilon^{142}\text{Nd}$ versus present-day source $\epsilon^{143}\text{Nd}$ diagram (Fig. 3B), NWA 7635 is indistinguishable in its isotope characteristics from the linear source mixing trend defined by the other shergottite data. The slope of the data array defines an apparent $^{142}\text{Nd}-^{143}\text{Nd}$ age of 4504 ± 6 Ma, identical to that reported in the study by Borg et al. (11). Although the nakhlites and chassignites are evidently derived from mantle sources distinct from those of shergottites (16), the isotope data presented here do not indicate that NWA 7635 is derived from mantle sources that are different from those that produced the other depleted shergottites. NWA 7635 is derived from Mars mantle source mixtures that are the most ITE-depleted, yet it shares mantle source characteristics with other shergottites.

The mantle source similarities between NWA 7635 and other depleted shergottites permit the inference that all of them may be derived from the same magmatic center on Mars. Our ejection age of NWA 7635 is identical to that determined for at least 10 other ITE-depleted shergottites (17–19); the mean of these 11 ejection ages is 1.1 ± 0.2 My (Fig. 4). Cosmogenic nuclide studies indicate three separate ejection events for depleted shergottites overall: one around 1 My (the event accounting for most of the depleted shergottites ($n = 11$)), one around 3 My (an event that launched depleted shergottites NWA 5990, NWA 7032, and QUE 94201), and one distinctly old launch event around 18 My for Dhofar 019 (17, 18, 20, 21). The meteorites having a 1.1-My ejection age consist of 11 depleted shergottites, including NWA 7635, but have no intermediate or enriched shergottites. The identical ejection ages and similar mantle source compositions for the group of 11 depleted shergottites strongly suggest that they were all launched from Mars by a single impact.

The igneous crystallization ages of depleted shergottites that have 1-My ejection ages range between 348 Ma and 2.4 billion years ago (Ga) (6, 7, 22–27), which spans close to half of Mars’ history. This long span of crystallization ages for these depleted shergottites suggests that there was at least 2 billion years of magmatic activity near the proposed ejection site on Mars. A crater-counting chronology, based on recently acquired high-resolution images, indicates that calderas on major volcanoes from the Elysium and Tharsis regions on Mars have undergone repeated activation and resurfacing (28–30). Both the Elysium and Tharsis volcanoes evidently formed before 3.6 Ga, followed by episodes of subsequent volcanic eruptions (lava flows). Crater-counting ages of some of those volcanoes indicate activity spanning more than 3 billion years (that is, Alba Mons, Biblis Tholus, Jovis Tholus, U兰uins Mons, and Hecates Tholus), suggesting a long history of active volcanism from spatially restricted sites on Mars (30, 31). The long activity of Martian volcanic centers from sample and crater chronologies confirms the very long-lived mantle plume dynamics in Mars (32, 33).

Shergottites and ALH 84001 (12) share mantle radiogenic isotopic characteristics, implying that they are part of the same overall mantle-melting environment, in contrast to that producing the nakhlites and chassignites (16, 34). Mantle convection that evidently drove this long-lasting Martian magmatism was ineffective in mixing early-formed and distinct mantle reservoirs, largely because of a lack of toroidal flow and relatively stable convection cell boundaries in the mantle (32).
MATERIALS AND METHODS

A total of 2.2 g of interior material was used for isotope analyses. Petrographic analyses and major and trace element concentration measurements of constituent phases were made from a representative polished thick section of the type material. Before disaggregation for mineral picking, the rock fragments were washed in an ultrasonic bath with ultrapure H₂O for 5 min to remove any surficial contamination. The fractions analyzed for Lu-Hf, Sm-Nd, and Rb-Sr isotopes were spiked with ¹⁷⁶Lu-¹⁷⁷Hf, ¹⁴⁹Sm-¹⁵⁰Nd, and ⁸⁷Rb-⁸⁴Sr isotope tracers before column chemistry following procedures outlined in the studies.
Fig. 4. Summary of Mars ejection ages for depleted, intermediate, and enriched shergottites. Data (with modified classification terminology) from fig. 14 of Herzog and Caffee (41), with the addition of data from Wieler et al. (17) and this work. The group of 11 depleted shergottites with 1-My ejection ages (including NWA 7635) defines an average age of 1.1 ± 0.2 My (95% confidence) shown as the vertical gray box. These data show that only depleted shergottites were ejected at 1.1 Ma.

Cosmogenic nuclide concentrations of \(^{10}\text{Be}\) and \(^{26}\text{Al}\) were measured by accelerator mass spectrometry at Purdue University (37), and concentrations of \(^{14}\text{C}\) were measured at the University of Arizona (38). The measured activities were 9.7 ± 0.1 dpm \(^{10}\text{Be}\)/kg, 70 ± 5 dpm \(^{26}\text{Al}\)/kg, and 46 ± 1 dpm \(^{14}\text{C}\)/kg. The cosmic-ray exposure age of 1.0 ± 0.1 My was based on \(^{10}\text{Be}\) and \(^{26}\text{Al}\) concentrations, the chemical composition of the measured sample, and model production rates (39). This age agreed with the noble gas exposure age of 1.4 (±0.4) My (39) and agreed with the noble gas exposure age of 1.4 (±0.4) My (39).

Acknowledgments: We are grateful to S. Kuehner for mineral analyses, E. L. Berger of NASA–Johnson Space Center for x-ray element maps, R. Conrey for x-ray fluorescence analyses, G. Chen for trace element analyses, and K. Ziegler for oxygen isotope analyses. We thank three anonymous reviewers for their detailed comments that improved the manuscript and editor K. Hodges. Funding: This work was supported by NASA Mars Fundamental Research (NNX11AF52G to T.J.L.), NASA Cosmochemistry (NNX12AX96G and NNX09AC06G to T.J.L. and NNX14AK62G to K.N.), and NASA Astrobiology (NNA13AA94A to B.L.B.). Author contributions: T.J.L., M.R., and R.A. measured the Sm-Nd and Lu-Hf isotopic compositions, interpreted the data, and drafted the manuscript. A.J.I. provided the sample material, measured the major element compositions, conducted the petrographic analyses, interpreted the data, and edited the manuscript. B.L.B. and A.M.S. measured the Rb-Sr isotopic compositions, interpreted the data, and edited the manuscript. K.N., A.J.T.J., and M.W.C. measured the cosmogenic nuclide concentrations, interpreted the data, and edited the manuscript. Competing interests: The authors declare that they have no competing interests. Data and materials availability: All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors.
