From time-resolved atomic-scale imaging of individual donors to their cooperative dynamics

Philipp Kloth and Martin Wenderoth*

The key elements in the steady miniaturization process of cutting-edge semiconductor devices are the understanding and controlling of charge dynamics on the atomic scale. In detail, we address the study of charging processes of individual doping atoms and, especially, the interaction of those atoms with their surroundings. We use pulsed optical excitation in combination with scanning tunneling microscopy at the n-doped gallium arsenide [GaAs (110)] surface to investigate single donor dynamics within a nanoscaled, localized space charge region. Tuning the tunnel rate can drive the system into nonequilibrium conditions, allowing distinction between the decay of optically induced free charge carriers and the decay of donor charge states. The latter process is atomically resolved and discussed with respect to donor-level binding energies and local donor configurations.

INTRODUCTION

Optical excitation of a semiconductor generates electron-hole pairs. Besides simple recombination, the presence of local fields and structural inhomogeneities can result in complex relaxation pathways (1). This process includes not only field-driven charge transport but also the interaction with local defects. Up to now, access to the correspondent microscopic processes is usually limited to probing a large volume of the host material (2, 3). On the macroscopic scale, a standard indicator, characterizing dynamic properties of charge processes inside a semiconductor, is the surface photo voltage (SPV). SPV describes the change of local potentials due to the presence of photo-generated charge. Microscopically, the buildup of an SPV is linked to various mechanisms such as the dynamics of dopants and the optically excited, freely movable carriers within the semiconductor. Especially, the controlled charging and discharging of individual dopants is the most elementary process in semiconductor electronics. In state-of-the-art device development, switching is already accomplished by a handful of donors (4–6). In this context, disorder, for example, the specific configuration of doping atoms, is crucial. SPV studies have already reported a significant inhomogeneity of the static properties (7, 8) on the atomic scale. Apart from its relevance in fundamental research, an atomic-level view on charge dynamics is needed for further device miniaturization. In particular, determining the influence of boundaries—for example, surfaces or internal interfaces—will substantially improve our understanding of dynamic properties of semiconductor nanostructures.

Here, we demonstrate the necessity for atomically scaled analysis of locally very inhomogeneous charging dynamics of individual donors, which, up to now, have usually been described by a single decay constant. We have used an optical pump-probe technique combined with scanning tunneling microscopy (STM) (SM) (9, 10) for more details, please see Materials and Methods) by applying the shaken-pulse-pair excitation (SPPX) (9–11) procedure. A periodic modulation of the optically induced tunnel current dl as function of the delay time td between pump and probe pulse represents the time evolution. Our sample system, sketched in Fig. 1A, is the STM tip-induced electrostatic potential (color-coded) (12) in silicon-doped GaAs (gallium arsenide, n-type), including the influence of optically excited electron-hole pairs. Comparable to the situation inside a Schottky contact, the electric field separates free charge resulting, at positive bias voltages, in an accumulation layer of holes at the surface. In return, initially ionized donors capture electrons and become neutral. The shift of the surface potential due to the presence of the photo-generated holes, leading to an increase of the tunnel current at the same bias voltage, is called SPV. The relaxation mechanisms of the donors and the electron-hole pairs plus their mutual interaction define the steady state of the charge configuration (13, 14). Additionally, previous studies have shown that tunneling electrons can address and thereby directly annihilate the photo-generated and accumulated holes at the surface (15, 16). Using the tunnel current I0 as an additional control parameter, we drive the system into different non-equilibrium conditions.

RESULTS

Figure 1B shows a multitude of dl(td) spectra (bias voltage Ub = 1.0 V) for increasing tunnel currents I0. As a unique feature, and in contrast to previous studies (10, 11), we applied low laser intensities P0, resulting in a positive optically induced current dl. The correlation between P0 and dl and the measuring process of dl itself are explained in detail in Materials and Methods. dl under pulsed excitation consists of the increase of conduction band tunneling dlC due to the buildup of the SPV and the tunneling into valence band states dl due to the presence of the accumulated photo-generated holes at the surface (Fig. 1C). Our study on continuous excitation has shown that the change dlC is likely to be the dominant effect (15). However, the percentages of dlC and dl on dl depend in detail on parameters such as STM tip shape, bias voltage, tunnel current, and excitation intensity. At I0 smaller than 250 pA, we observe an exponential decay of dl(td) = I0exp[−(1/τ)td] with a decay constant τ decreasing with increasing I0 (Fig. 1E, red dots). We attribute this I0 dependency of τ to the tunnel process I0 into photo-generated holes inside the valence band. Note that the size of the space charge region changes when decreasing the tip-sample distance for increasing I0. However, for a tip movement of 1 to 2 Å (current range in Fig. 1B for a usual tunnel barrier height of 4 eV), this effect is negligible (see fig. S1). Consequently, the decay of dl(td) is determined by the annihilation process of the accumulated holes at the surface. By adjusting I0, we are able to actively control this decay, in the following termed as τhole.

At I0 = 450 pA, the line shape of dl(td) changes notably. Although dl remains positive for a small td and decays fast, it alters its sign for a larger td. This effect gets even more pronounced for higher currents (500 pA) until a completely negative and exponentially decaying dl(td) is observed (1000 and 1500 pA). We explain the line shape of dl(td) at
higher currents with a crossover between two relaxation processes. The hole annihilation dominates at low and medium $I_0$ (Fig. 1C). The negative $dl$ can be identified as the signature of donor ionization by electron emission from the donor level into the conduction band (Fig. 1D, green arrow). During the relaxation to the ground state, $dl(t_d)$ < 0 reflects a special nonequilibrium condition. For high $I_0$, holes are annihilated rapidly, whereas donors remain neutral (for more details on the nonequilibrium condition, see fig. S2). Consequently, at the surface, nearly no net charge is found, the potential difference between the tip and the surface is present, leading to a vanishing $t$. Note that in (C) and (D), the same bias voltage is applied. (E) Decay constant $t$ plotted against current $I_0$ in case of positive and negative $dl$. The dashed lines are intended as a guide to the eye.

Fig. 1. Charge dynamics at the n-doped GaAs(110) surface. (A) The STM tip induces a space charge region below the GaAs(110) surface, leading to the separation of photo-generated electron-hole pairs. The presence of holes beneath the tip modifies the charge configuration at the surface. (B) The optically induced current $dI$ as a function of the delay time $t_d$ reveals an altering sign from positive to negative values going from low to high tunnel currents (bias voltage, 1.0 V; excitation parameters: repetition cycle, 8 µs; pulse width, 40 ns; average power, 10 µW). The lines are intended as a guide to the eye. (C) Band tunneling scheme for $t < \tau_{\text{hole}}$. At low tunnel currents, $dl(t_d)$ is dominated by the hole annihilation process at the surface via $I_v$. (D) Band tunneling scheme for $\tau_{\text{hole}} < t < \tau_{\text{don}}$. For high currents, holes at the surface are annihilated fast, whereas surface-near donors still have to emit their electrons into the conduction band to ionize (green arrow). Nearly no net charge at the surface is present, leading to a vanishing $l$. (E) Decay constant $t$ plotted against current $I_0$ in case of positive and negative $dl$. The dashed lines are intended as a guide to the eye.
The binding energy $E_B$ and the local field $E$ at the donor position determine the electron emission rate for this tunneling process. To cross-check this $E_B$ dependency, we compare the experimental $\tau_{\text{don}}$ quantitatively with the ionization times $t_{\text{hydro}}$ calculated for hydrogen atoms in an electric field (19) with adapted parameters for silicon donors in bulk GaAs (Fig. 3A and fig. S8). For comparison, the found pairs of $E_B$ and $\tau_{\text{don}}$ for the three different dopant depths below the surface in Fig. 2A are included in Fig. 3A. Nearly no charge and hence a weak electric field at the surface characterize the relaxation from the nonequilibrium conditions at high currents $I_0$ (Fig. 1D). Charge fluctuations of donors and thereby field fluctuations take place (17, 20), triggering further field-driven ionizations. We model an electrostatic potential in a cross section at the GaAs surface (Fig. 3B and C), including random donor positions in charged (blue dots) or neutral (green dots) state, according to the doping density of our sample ($3 \times 10^{18}$ cm$^{-3}$, 7 nm average distance between two donors). To estimate the probability of charging events, we calculated exemplary Coulomb potentials of ionized donors in this half-space geometry.

Regarding the ionization process of donors with a binding energy $E_B$ of 10 meV and a $\tau_{\text{don}}$ of 237 ns (Fig. 3B, blue/white dot), the required field $E$ of 0.2 mV/nm will already be given if any of the donors in a spherical volume marked by the white contour line in Fig. 3B ionizes. In contrast, to charge a donor with a binding energy $E_B$ of 45 meV and a $\tau_{\text{don}}$ of 530 ns (Fig. 3C, red/white dot), a field $E$ of 2.5 mV/nm is needed. The radius of the correspondent volume reduces to 8 nm (Fig. 3C, white contour line), and consequently, the number of possible donor candidates decreases, making the ionization process unlikely. We deduce that the variation in $E_B$ cannot be the only reason for the variation of $\tau_{\text{don}}$. In fact, we expect a considerable increase of the ionization probability when more than one donor is involved. From this deduction, we propose a relaxation to the ground state as a stepwise buildup of the electric field, starting with the ionization of donors positioned in the bulk material and continuing to donors near the surface. Hence, the donor dynamics cannot be treated as individual charging and discharging processes connected to a dedicated decay constant $\tau_{\text{don}}$. Instead, they have to be regarded as a stochastically distributed ensemble of linked subsequent charging events.
triggered by random charge fluctuations. Thus, the actual relaxation dynamics will vary from one local donor configuration to another.

DISCUSSION
We are convinced that this coupled charging dynamics of individual donors, including the influence of surfaces and interfaces, can have a massive impact on the functionality of semiconductor devices. Bistabilities in the charge state of coupled donors have already been observed in the millisecond time regime (17). The map for the relaxation time of individual donors in Fig. 2C shows nonisotropic local enhancements of $t_{\text{don}}$, indicating the interaction among themselves. Continuous charging and discharging events are responsible for shot noise in semiconductor devices (21), but are not yet experimentally resolved on the local scale. Even quantum computer approaches discuss single donors as isolated qubits (22–24). Ultimately, in all these subjects, only an atomic-scale characterization can provide a detailed understanding. In this context, pulsed optical excitation combined with STM opens up an exciting research field with a myriad of applications.

MATERIALS AND METHODS
Experimental setup and sample system
All data were recorded in a home-built low-temperature, ultrahigh vacuum STM at a base pressure of $1 \times 10^{-10}$ mbar and at base temperatures of 77 and 6 K. The bias voltage was defined as the sample voltage. The silicon n-doped GaAs ($3 \times 10^{18}$/cm$^3$) crystals were chemically thinned down to 100 $\mu$m and cleaved inside the vacuum chamber exposing the (110) surface. The optical setup, implemented in the STM, is shown in Fig. 4. The laser beam of a continuous-wave laser diode (Toptica, 785 nm) was processed into a pulse shape with the help of an electro-optic modulator (EOM), controlled by a high-frequency pulse generator. After focusing the pulses into the tunnel junction, the optically induced signal is extracted by lock-in amplification.

Excitation state–dependent sign of the optically induced current $dl(t_d)$
The quantity $dl(t_d)$ is the difference in the tunnel current induced by a sequence of two shortly separated pulses compared to the current induced by a train of two well-separated pulses. In comparison to other pump-probe experiments, the pump and the probe pulse have identical intensities and both trigger the same mechanism: a change in the tunnel current. In contrast to our studies, $dl$ in previous optical pump-probe SPV measurements had a negative sign (9–11). We show that different excitation states after the pump pulse ($t = t_{PW}$) determine the sign of $dl$. Figure 5 schematically shows two shortly separated optical pulses (Fig. 5A, green), discusses a saturated (Fig. 5B, blue) and a nonsaturated excitation case (Fig. 5C, red), and compares this with the excitation induced by two well-separated double pulses (Fig. 5D).
If the pump pulse has induced the maximum change in the tunnel current \( I_1 \) (Fig. 5B), the effect of the probe pulse on the tunnel current will be at maximum of the same order. Because of the overlap in the decay (deep blue shading), the average current was less than the average current (black dashed lines) induced by two well-separated pulses (Fig. 5D). As per definition, this leads to a negative \( dI \). If the first pulse does not induce the maximum effect, the shape of the system response, triggered by the second pulse, can change considerably. Figure 5C shows the configuration for which the excitation by the probe pulse leads to more tunnel current (light red shading) in comparison to one single, isolated pulse. In the differential measuring method of the averaged signal (black dashed line), this may lead to a positive \( dI \).

Experimentally, saturation (Fig. 5B) or nonsaturation (Fig. 5C) in the excitation state can be investigated by applying different laser intensities \( P_1 \) [Fig. 6A, red (low excitation intensity) and blue (high excitation intensity)]$. The time to obtain saturation for the charge configuration at the surface is connected to the time it takes for a donor to capture one of the photo-generated electrons and to become neutral subsequently. At higher \( P_1 \), the electron density at the surface is denser and, consequently, the SPV builds up faster during the pump pulse. The current dependency of the decay constants extracted from \( d\langle d \rangle \) spectra is identical for high and low excitation intensity (Fig. 6B). This is a clear indication that in each case, the same relaxation mechanism is probed, namely, the annihilation of the holes via tunneling. The only difference in both cases is the excitation state of the charge configuration at the surface after the pump pulse, resulting in the sign alteration of \( dI \).
