Magnetic skyrmions are topologically protected whirls that decay through singular magnetic configurations known as Bloch points. We used Lorentz transmission electron microscopy to infer the energetics associated with the topological decay of magnetic skyrmions far from equilibrium in the chiral magnet Fe₁₋ₓCoₓSi. We observed that the lifetime $\tau$ of the skyrmions depends exponentially on temperature, $\tau \sim \tau_0 \exp(-E/RT)$. The prefactor $\tau_0$ of this Arrhenius law changes by more than 30 orders of magnitude for small changes of the magnetic field, reflecting a substantial reduction of the lifetime of skyrmions by entropic effects and, thus, an extreme case of enthalpy-entropy compensation. Such compensation effects, being well known across many different scientific disciplines, affect topological transitions and, thus, topological protection on an unprecedented level.

INTRODUCTION

A question studied in many fields of the natural sciences concerns the lifetime of metastable states. Thermal activation across energy barriers governs (for example, chemical reactions) the lifetime of memory elements in computers and in hard disks and the transport of ions and electrons in disordered media. Often, these processes are controlled by a characteristic energy, the activation energy. However, it has also been established that a large number of different pathways across an activation barrier lead to a large entropy correction, reducing the lifetime of metastable states and, thus, the importance of the energy barriers. This effect is known as enthalpy-entropy compensation in the context of chemistry or the Meyer-Neldel rule in material sciences. Enthalpy-entropy compensation has, for example, been observed for catalytic reactions (1), transport in semiconductors (2, 3), biological processes (4), and in many other fields (5, 6).

In recent years, differences of the topology of physical states have been widely portrayed as providing exceptionally high stability. Topology represents a branch of mathematics concerned with those properties of geometric configurations that are unaffected by smooth deformations. Famous examples for topologically nontrivial objects include superconducting vortices, certain magnetic textures, structural defects and surface states of topological materials. However, despite this abundance of topologically nontrivial configurations in nature, an unresolved key question concerns their stability when being part of an ensemble far from equilibrium.

Skyrmions in spin systems with chiral interactions are particularly suitable to clarify this issue, because a well-founded highly advanced theoretical understanding exists in excellent agreement with the experiment. Representing topologically nontrivial spin whirls, skyrmions were experimentally first identified in the B20 compounds MnSi and Fe₁₋ₓCoₓSi (7, 8), followed more recently by a wide range of bulk compounds (9–11), surface- and interface-based systems (10, 12–14), as well as hetero- and nanostructures (15, 16). With typical dimensions from a few up to several hundred nanometers, skyrmions in magnetic materials are accessible to a wide range of experimental techniques. Moreover, they are also of immediate interest for spintronics applications. At present, this concerns foremost memory elements (15, 17, 18), where lifetimes exceeding 10 years represent the technical requirement. In turn, the design of metastable states with long lifetimes is both mandatory and a major motivation for the study reported here.

RESULTS

Here, we have chosen the B20 compound Fe₁₋ₓCoₓSi with $x = 0.5$, which displays a well-understood bulk phase diagram that is generic for this class of materials (7, 8, 19, 20). With decreasing temperature, a paramagnetic to helimagnetic transition occurs at $T_c$. A lattice of skyrmion lines forms in a small field and temperature window just below $T_c$, as first established by small-angle neutron scattering (SANS) (8). Lorentz force transmission electron microscopy (LTEM) in Fe₁₋ₓCoₓSi provided real-space images of the skyrmions (21). Although the skyrmion phase in bulk materials is thermodynamically stable only in a small pocket of phase space, it was shown early on that the range of stability, albeit being hysteretic, increases markedly and extends down to zero temperature in ultrathin bulk samples (21–23). A typical phase diagram obtained from our sample when cooling at a fixed magnetic field and followed by an increase or a decrease of the field at a fixed low temperature is shown in Fig. 1A. In the red shaded region, the skyrmion lattice is stable on experimentally relevant time scales but decays when the magnetic field is increased or decreased further.

Schematic depictions of typical spin configurations during the early stages of the decay into a ferromagnetic state under increasing field or into a helical state under decreasing field are shown in Fig. 1 (C and D). The decay into the helical state was first addressed by means of magnetic force microscopy (MFM) of the surface of a bulk sample of Fe₁₋ₓCoₓSi ($x = 0.5$) (24). Here, the decay was found to occur by a merging of skyrmions, implying the presence of a Bloch point that acts like a zipper between skyrmions, that is, a point of vanishing magnetization enabling the unwinding of the nontrivial topology (Fig. 1D). In comparison, the decay into the conical or ferromagnetic state is theoretically predicted to take place by a pinching-off through the creation of a pair of Bloch points, as shown in Fig. 1C, and the subsequent motion of the Bloch points toward the surface (23, 25). Several studies had reported hysteretic and metastable skyrmion states. Early SANS studies on bulk samples of Fe₁₋ₓCoₓSi revealed the possibility to super-cool the skyrmion lattice into a metastable state (8, 26). Detailed magnetization and ac susceptibility measurements combined with SANS showed (27) that the super-cooled skyrmion...
lattice order for temperatures below ~10 K may only be destroyed by means of an applied magnetic field exceeding the conical to ferromagnetic transition field, that is, at low temperatures, thermal activation is not sufficient to trigger a decay of the metastable skyrmion state. The observation of sizeable supercooling effects in MnSi under pressure (28) or after violent quenches exceeding 400 K/min (29), and, in Cu2OSeO3, under electric field cooling (30), and the observation of slow relaxation at low temperatures in GaV5S9 (31) underscore the generic existence of supercooling effects noticed first in Fe1−xCoSi. Several studies also investigated skyrmion generation and destruction triggered by electric currents (16, 32, 33). The energy barrier for skyrmion creation/annihilation in two dimensions was studied theoretically in the studies by Bessarab et al. and Hagemeister et al. (34, 35) and was extended to three dimensions by Rybakov et al. and Schütte et al. (23, 25). An elegant approach to explore the energetics requires time-resolved real-space imaging of large ensembles.

Fig. 1. Magnetic phases and skyrmion decay in Fe1−xCoSi. (A) Magnetic phase diagram of Fe1−xCoSi with x = 0.5 obtained by first cooling the system at a fixed magnetic field, B = 23 mT, and then raising or lowering the field at fixed temperature T. The decrease in the applied field triggers the decay into a helical configuration, whereas either a conical or ferromagnetic state is reached for an increase of the field. (B) Typical LTEM images of helical and skyrmion lattice order, respectively. (C) Schematic image of an early state of the decay of the skyrmion lattice toward a ferromagnetic state. The skyrmion splits by the formation of a pair of Bloch points located at the end of the skyrmion strings, which move toward the surface. (D) Decay of skyrmion lattice order toward the helical state. Neighboring skyrmions merge, and a Bloch point at the merging points moves toward the surface.

Here, we used time-resolved LTEM on thin bulk samples of Fe1−xCoSi. On the one hand, this method provides the required spatial and temporal information, without driving the skyrmion decay. On the other hand, and as explained above, Fe1−xCoSi represents an extremely well-understood and well-characterized material suitable to address these issues.

For our measurements, a sample with a thickness of d = 240 nm was prepared using a focused ion beam (FIB) from the same optically float-zoned single crystal studied before (24, 26). The single crystal was cut such that a (100) axis was normal to the platelet. The magnetic field was applied along the same direction. As shown in Fig. 1B, for zero magnetic field and low temperatures, a well-defined helical order is observed with a modulation length λ ≈ 90 nm, in agreement with previous reports. Furthermore, under field cooling in an applied field of 23 mT, a well-defined hexagonal skyrmion lattice forms just below TC. When reducing the temperature further, the same unchanged skyrmion lattice persists down to the lowest temperatures studied (12 K).

In our LTEM measurements, the evolution of the magnetic state was studied with a time resolution of ~100 ms, where movies were recorded after field cooling and a subsequent field change. We first investigate the destruction of the skyrmion state when the magnetic field is decreased. Shown in Fig. 2 are typical data for a decay into the helical state observed after field cooling at 23 mT down to Tm = 16.7 K and a reduction of the field to Bm = −2.6 mT. As illustrated in Fig. 2 (A to C) for patterns recorded at t = 0.1, 4.8, and 20.2 s after reaching Bm, respectively, the intensity pattern displays a merging of the skyrmions. This process corresponds accurately to the mechanism observed by means of MFM on the surface of bulk specimens cut from the same single crystal (24).

The merging of skyrmions is additionally illustrated in Fig. 2D, which displays the intensity across the white box in panels (A) to (C) as a function of time along the vertical axis. Details of the merging cannot be resolved for the frame rate of our experiments, that is, the motion of the monopoles across the 250-nm thickness of the sample is faster than 100 ms corresponding to a speed greater than 2.5 × 106 m/s. However, by using a bespoke algorithm, we could track the number of skyrmions N for a given area as a function of time as illustrated in Fig. 2E. As a main new result, we observe an exponential time
dependence, \( N \approx N_0 \exp \left( -\frac{t}{\tau(T)} \right) \) (blue line), from which we extract the lifetime, \( \tau(B, T) \), as a function of field and temperature, analyzed further below. Note that \( N_0 \) is, in general, smaller than the initial number of skyrmions, because some skyrmions have already decayed during the field sweep when only blurred images are recorded because of image drifts.

The destruction of the skyrmion state after field cooling, when an increase in magnetic field triggers a decay into a conical (or ferromagnetic) state, is summarized in Fig. 3. Data shown were recorded after field cooling at 23 mT down to \( T_m = 18.5 \) K and an increase of the field to \( B_m = 57 \) mT. As predicted by theory (23), the decay pattern is characterized by the disappearance of individual skyrmions, as opposed to the merging observed for a decay into the helical state. Figure 3D displays the intensity across the white box in panels (A) to (C) as a function of time along the vertical axis. Using the same algorithm to track the number of skyrmions again, an exponential time dependence is observed for the entire parameter range accessible, as shown in Fig. 3E. Both the qualitative decay mechanism and the specific time dependence analyzed below represent the main results of our study.

We note that for most of the decays, individual skyrmions vanish suddenly between two frames of our movies. However, for less than 10% of skyrmions, the intensity does not vanish in a single step but exhibits a two-step process. An example is marked by the red dashed circle in Fig. 3 (A to C), corresponding to a diameter of \( \sim 100 \) nm in Fig. 3D. The relative change of intensity in this region, \( I/I_0 \), as a function of time is shown in Fig. 3F. The observation of the intermediate level implies that part of the skyrmion survives as an intermediate, metastable skyrmion string with a length shorter than the thickness of the sample. At least one end of the string is, therefore, inside the sample, and topology enforces the presence of a Bloch point at this location. In turn, the metastable state consists of at least one Bloch point and a skyrmion string that either connects one Bloch point (or two) to the surface or connects a pair of Bloch points which each other.

One of the most likely mechanisms causing the metastable intermediate state is trapping of the Bloch points by local defects. As an interesting alternative, the metastable state may be a so-called chiral bobber, predicted theoretically by Rybakov et al. (23). The authors of this study pointed out that the surface energy of the skyrmion provides a repulsive potential for the Bloch point. Thus, a chiral bobber represents a Bloch point located immediately below the surface of the sample. To clarify the nature of the metastable states we observed, we analyzed the intensity of 18 of these inhibited decays (out of the 355 decays we investigated in detail). By plotting the number of inhibited decays as a function of relative intermediate intensity shown in Fig. 3G, we observe a very broad distribution. Taking these intensities as a measure of the length of the intermediate states, most of them are larger than expected theoretically for a single bobber located close to the surface. Hence, within our limited statistics, an interpretation in terms of Bloch points trapped by defects appears to be the most likely scenario.

**DISCUSSION**

Taking together all of our data, the lifetime \( \tau(B, T) \) of skyrmions depends sensitively on the magnetic field and the temperature. Shown in Fig. 4A are typical decay times as a function of temperature for selected field values. The phase diagram shown in the background of that figure is identical to Fig. 1A. On a double-logarithmic scale, the decay times as a function of thermal energy display strong variations with magnetic field, where the decay into the conical and helical states is shown in Fig. 4 (B and C), respectively. As expected, the temperature dependence can be described approximately by an Arrhenius law, \( \tau(B, T) \approx \tau_0 \exp[\Delta E(B)/k_B T] \). However, the energy barriers vary strongly with the strength of the magnetic field, the largest being close to the stability regime of the skyrmion lattice. The energy barrier therefore drops for increasing field, for example, from \( \Delta E = (199 \pm 4) \) meV...
values of energy for increasing and decreasing magnetic fields, respectively, and various transition into the helical state. Using straightforward scaling arguments for a transition into a conical state. As in our experiments, theoretically (see the Supplementary Materials) to extrapolate the calculated activation energies to the experimentally relevant parameter regime, we find, however, that the measured activation energies are about an order of magnitude smaller than the predicted ones. At present, we have no explanation for this substantial discrepancy; however, we speculate that it is connected with the large entropic effects discussed below, which become most pronounced for large activation barriers.

Surprisingly, measurements of the activation energies alone do not allow for the prediction of the lifetime of the metastable skyrmion state. Instead, we find that the prefactor \( \tau_0(B) \)— the so-called attempt time—of the Arrhenius dependence assumes extremely small values and shows an unusually strong sensitivity to magnetic fields. This is emphasized in Fig. 4D, which shows that \( \tau_0 \) as a function of the activation energy, changes from extremely low values, smaller than \( 10^{-37} \) s, for the measurements at \( B_m = 22.2 \) mT, where the largest activation energy was measured, to almost macroscopic time scales \( 10^{-2} \) s at \( B_m = 57 \) mT. These values should be contrasted with typical microscopic time scales \( \sim 10^{-9} \) s commonly accepted for estimates of attempt times in magnetic materials (36–38).

To account for this extreme variation, we revisit the Arrhenius law used for fitting the decay times. At finite temperature, thermodynamics and transition rates are governed by the free energy \( F(T, B) = E(T, B) - T \cdot S(T, B) \). Thus, the Arrhenius-type decay law for a single energy barrier assumes the form \( \tau(B) = \tau_0 \exp \left( \frac{\Delta E(T, B)}{k_B T} \right) \), where \( \Delta F = F_b - F_0 \) is the free-energy difference of the initial state, \( F_0 \), and a highly excited state, \( F_b \), which defines the bottleneck of the skyrmion decay. Inserting the definition of the free energy one obtains

$$
\tau(B) = \tau_0 \exp \left( -\frac{\Delta S(B)}{k_B} \right) \exp \left( \frac{\Delta E(B)}{k_B T} \right) \tag{1}
$$

In turn, the high-energy offset of the decay time, given by \( \tau_0 = \tau_0 \exp \left( -\frac{\Delta S(B)}{k_B} \right) \), depends exponentially on the entropy difference, \( \Delta S \), between the skyrmion state and the bottleneck state. A large positive value of \( \Delta S \) leads to an exponential reduction of \( \tau_0 \) and strongly increases the transition rates. Physically, this is due to the exponentially large number \( N_p \) of microscopic pathways across the energy barrier, \( \Delta S = k_B \ln [N_p] \), which increases the transition rate by the factor \( N_p \). Similarly, a negative value of \( \Delta S \) takes into account a reduction of the transition rate, which arises when the number of microscopic realizations of the initial state with skyrmion is much larger than the number of states close to the bottleneck.

Similar entropic effects as discussed here occur in many different systems in biology, chemistry, and physics. Because the high-energy states typically have a larger entropy, these entropic effects tend to partially counterbalance the energetic effects. Therefore, this phenomenon is often referred to as the “compensation effect.” Phenomenologically, linear relationships of activation energy and entropy are known as the Meyer-Neldel rule in the context of solid-state physics (2, 5, 6). In the limit where the activation energy is much larger than the typical microscopic energy scale \( E_m \), they arise (5, 6) because the number of ways the activation barrier can be reached by microscopic processes varies exponentially in \( \frac{k_B}{2 \mu \nu} N_p \sim \exp \left( \frac{\Delta S}{k_B T} \right) \) and hence \( \Delta S \sim k_B \frac{\Delta E}{E_m} \). The fit in Fig. 4D shows that \( \tau_0 \) follows the Meyer-Neldel rule approximately and exhibits an exponential dependence on the activation energy \( \Delta E \). From the fit, we obtain \( \frac{\Delta E}{E_m} \approx 27 \pm 3 \) K, which is of the correct order of magnitude expected for our system where \( T_c \approx 38 \) K. Remarkably, the approximate
linear relation of $\Delta S$ and $\Delta E$ extends even in the regime where $\tau_0$ is much larger than microscopic time scales, strongly suggesting a negative $\Delta S$. Our study reveals unprecedentedly large compensation effects by more than 30 orders of magnitude for the decay of topologically non-trivial spin configurations, notably skyrmions, as part of an ensemble far from equilibrium. This may seem particularly relevant in view of the technological impact expected of topological protection. It concerns, for instance, specifically the long-term stability of magnetic memory devices inferred from measurements of activation energies. Whereas typical values of $\tau_0 \sim 10^{-9}$ s are broadly accepted (36, 37), our results show that, especially for the large activation energies required for long-term stability, these estimates may overestimate the thermal stability of skyrmion-based memory devices by factors of the order of $10^{20}$ and more. This illustrates that entropic effects will be very important for the technological exploitation of topologically nontrivial systems, such as memory technology based on skyrmions (39).
