

PLANETARY SCIENCE

Early formation of planetary building blocks inferred from Pb isotopic ages of chondrules

Jean Bollard,¹ James N. Connelly,¹ Martin J. Whitehouse,² Emily A. Pringle,³ Lydie Bonal,⁴ Jes K. Jørgensen,¹ Åke Nordlund,¹ Frédéric Moynier,³ Martin Bizzarro^{1,3*}

The most abundant components of primitive meteorites (chondrites) are millimeter-sized glassy spherical chondrules formed by transient melting events in the solar protoplanetary disk. Using Pb-Pb dates of 22 individual chondrules, we show that primary production of chondrules in the early solar system was restricted to the first million years after the formation of the Sun and that these existing chondrules were recycled for the remaining lifetime of the protoplanetary disk. This finding is consistent with a primary chondrule formation episode during the early high-mass accretion phase of the protoplanetary disk that transitions into a longer period of chondrule reworking. An abundance of chondrules at early times provides the precursor material required to drive the efficient and rapid formation of planetary objects via chondrule accretion.

INTRODUCTION

The discovery of thousands of exoplanets orbiting Sun-like stars (1) establishes that planet formation is a ubiquitous process in the galaxy. In the standard model (2), the formation of planets occurs in stages where small dust particles coalesce into 10- to 100-km-diameter planetesimals, which collide to form planetary embryos and planets over time scales of 50 to 100 million years (My). However, recent astronomical observations of young protoplanetary disks suggest much more rapid time scales for the growth of planetary cores. Detailed imaging of the <1-My HL Tauri protoplanetary disk in the submillimeter/millimeter domain has revealed the presence of ring structures that are interpreted to reflect the early stages of planet formation (3). These rapid time scales are in keeping with newer models of planet formation where planetary growth is fueled by pebble accretion, that is, the accretion of centimeter- to meter-sized particles loosely bound to the gas onto planetesimal seeds (4).

In the solar system, a record of the earliest stages of planet formation may be preserved in the most primitive meteorites (chondrites), which are fragments of asteroids that avoided melting and differentiation. The most abundant constituents of chondrites are chondrules, millimeter-sized glassy spherules formed as free-floating objects by transient heating events in the solar protoplanetary disk. Recent simulations indicate that the main growth of asteroids can result from the gas drag-assisted accretion of chondrules (5), a process analogous to pebble accretion. In these models, the largest planetesimals of a population with a characteristic radius of ~100 km undergo runaway accretion of chondrules forming Mars-sized planetary embryos within a time scale of ~3 My. If chondrules represent the building blocks of planetary embryos and, by extension, terrestrial planets, understanding their chronology and formation mechanism(s) is critical to determine at which point during the early evolution of the solar system were conditions favorable to form planetary bodies.

Of the various radiometric clocks, U-corrected Pb-Pb dating is the only method that provides a high-resolution assumption-free chronology of the first 10 My of the solar system. It is based on two isotopes

of U that decay in a chain to stable Pb isotopes, namely, ^{235}U to ^{207}Pb with a half-life ($T_{1/2}$) of ~0.7 billion years (Gy) and ^{238}U to ^{206}Pb with a $T_{1/2}$ of ~4 Gy. Using this approach, it has been recently demonstrated that chondrule formation started contemporaneously with the condensation of the solar system's first solids—calcium-aluminum-rich inclusions (CAIs)—at 4567.3 ± 0.16 My and lasted for ~3 My (6). However, this chronological framework is based on only five individual objects such that it is not possible to provide a statistically significant analysis of the tempo and full duration of chondrule production. To provide an accurate chronology of chondrule formation based on a significant number of objects, we have determined the Pb isotope compositions by thermal ionization mass spectrometry (TIMS) of 17 individual chondrules from primitive chondrite meteorites (Table 1), including the NWA 5697 ordinary chondrite and the NWA 6043 and NWA 7655 (CR2) carbonaceous chondrites. CR chondrites are considered to be one of the most primitive classes of meteorites, having experienced only mild aqueous alteration and showing no evidence for significant effects of thermal metamorphism (7). Moreover, analysis of the organic matter by Raman spectroscopy indicates that NWA 5697 is of petrologic type 3.10, that is, among the most pristine ordinary chondrites (see the Supplementary Materials). The Pb isotope analyses enable us to derive Pb-Pb dates through the internal isochron approach by combining multiple fractions obtained by sequential acid dissolution of individual chondrules. These data are complemented by in situ analyses of the Pb isotope composition of the various mineral phases acquired by secondary ionization mass spectrometry for a subset of these chondrules, which allows us to determine the nature of the carrier phase of uranium and, hence, radiogenic Pb in these objects. Finally, using multiple-collector plasma source mass spectrometry (MC-ICPMS), we have measured the $^{238}\text{U}/^{235}\text{U}$ ratio of seven individual chondrules (six of which have been Pb-Pb-dated) to test for potential U isotope heterogeneity, as well as the Zn stable isotope composition of seven chondrules to assess the thermal history of their precursors.

RESULTS

Pb-Pb isotopic ages of chondrules

The subset of chondrules we investigated comprises all major petrographic classes, including both porphyritic and nonporphyritic texture types, as well as FeO-rich and FeO-poor varieties (Table 1). The $^{238}\text{U}/^{235}\text{U}$ ratio measured for seven individual chondrules from

Table 1. Summary of Pb-Pb dates, petrology, μ values, and $^{238}\text{U}/^{235}\text{U}$ and Zn isotope compositions of individual chondrules. Pb isotope data for the Allende and three chondrules from NWA 5697 (C1, C2, and C3) were previously reported by Connelly *et al.* (6) and are included here for completeness. P, porphyritic; NP, nonporphyritic; I, type I; II, type II. The $^{238}\text{U}/^{235}\text{U}$ uncertainties are propagated in the final age uncertainties. The Pb-Pb isochrons for three chondrules (5-C1, 5-C4, and 1-C2) project back to a modern terrestrial composition, and thus, accurate μ values cannot be calculated for these objects. The zinc isotope compositions are reported in δ notation, which reflects the per thousand (‰) deviations of the $^{66}\text{Zn}/^{64}\text{Zn}$ of the sample from the JMC Lyon standard.

NWA 5697 returns values identical within analytical uncertainty to the solar $^{238}\text{U}/^{235}\text{U}$ value of 137.786 ± 0.013 (Table 1 and fig. S24), confirming the lack of U isotope variability among individual chondrules (6, 8, 9) at the resolution of our analyses. This observation validates the approach of using the solar $^{238}\text{U}/^{235}\text{U}$ value to calculate Pb-Pb dates of individual chondrules, although for completeness, we used the measured $^{238}\text{U}/^{235}\text{U}$ values to calculate chondrule ages for which both U and Pb isotope compositions were determined. The six chondrules with measured $^{238}\text{U}/^{235}\text{U}$ ratios define ages that span from 4567.61 ± 0.54 million years ago (Ma) to 4564.65 ± 0.46 Ma. This age range is comparable to that of 4567.57 ± 0.56 Ma to

4563.24 ± 0.62 Ma defined by the remaining 11 objects for which the solar $^{238}\text{U}/^{235}\text{U}$ value is used to calculate the Pb-Pb ages. Using the bulk $^{238}\text{U}/^{235}\text{U}$ of the host chondrites or, alternatively, bulk chondrule estimates of the same meteorites returns ages that are within 100,000 years of that obtained using the solar $^{238}\text{U}/^{235}\text{U}$ value of 137.786 ± 0.013 (table S7) and, hence, well within the uncertainties of the final ages we report. To better understand the significance of our Pb-Pb dates, we have measured the Pb isotopic compositions of the individual mineral phases for chondrules 1-C2 (NWA 7655) and 3-C1 (NWA 5697) using in situ methods (see the Supplementary Materials). Our analysis establishes that the radiogenically produced

Pb and, hence, U are mainly present in the fine-grained chondrule mesostasis, whereas the initial nonradiogenic Pb is predominantly hosted by sulfides enclosed in the mesostasis (fig. S25). The finding that the radiogenic Pb is present in the mesostasis is in keeping with partition coefficient data as U typically behaves as an incompatible element in most silicates (10). These results also agree with the systematics of the sequential acid dissolution approach used to define the Pb-Pb isochron ages, which reveals that the fractions with the most radiogenic Pb isotope compositions are released with the use of an acid mixture that preferentially dissolves nonrefractory silicate phases (see the Supplementary Materials). Thus, we infer that the Pb-Pb isochron ages of individual chondrules reflect the timing of crystallization associated with the last chondrule-melting event.

Our chondrule age data set based on the analysis of 22 individual objects demonstrates that the production and melting of chondrules began contemporaneously with CAI condensation and melting and continued for ~4 My (Fig. 1A). In Fig. 1B, we show the Pb-Pb age distribution of chondrules, which, at face value, indicates a progressive reduction in chondrule production rate through time. Approximately 50% of the chondrules investigated here formed within the first million years of the protoplanetary disk, suggesting that chondrule formation was more efficient in early times. The residence time of millimeter-sized solids in evolving disks is predicted to be extremely short relative to the typical lifetimes of protoplanetary disks as a result of aerodynamic drag (11). Although some mechanisms exist to limit the inward drift of millimeter-sized solids such as, for example, dust trapping, these operate on time scales typically shorter than the age variability reported here for chondrules (12). Thus, the presence of an ancient component and significant age variability among chondrules from individual chondrites (Fig. 1) require effective outward mass transport and/or storage of chondrules during the lifetime of the protoplanetary disk. Recycling of early-formed refractory solids such as CAIs during chondrule-forming events has been observed in a number of primitive chondrites (13–15). Together with petrological evidence suggesting that many chondrules experienced multiple melting events (16, 17), these observations raise the possibility that younger chondrule populations predominantly reflect the remelting and, hence, recycling of chondrules formed at earlier times.

Early chondrule formation and protracted recycling

It is well established that the flash heating events resulting in the melting of chondrules result in significant evaporative Pb loss and, hence, enhancement of the $^{238}\text{U}/^{204}\text{Pb}$ ratio (μ) relative to the solar value of ~0.19 given the refractory nature of U (6). This is consistent with the μ values for individual chondrules analyzed here that range from ~2 to ~183 (see Table 1 and the Supplementary Materials), which corresponds to up to ~99.94% of Pb loss relative to the solar composition. If the relatively high bulk μ values recorded by most of the chondrules were acquired early, it would lead to the accumulation of substantial amounts of radiogenic Pb during the lifetime of the protoplanetary disk. Thus, chondrules with protracted complex thermal histories involving more than one melting episode are expected to record evolved initial Pb isotopic compositions relative to objects formed from precursors with near-solar μ values. Figure 2A shows the back projection of the regressions for each of the individual chondrules dated in this study, which allows us to assess the initial Pb isotope compositions of these objects. The chondrule data set shows variable initial Pb isotope compositions corresponding to a range of ~120 ϵ units in the $^{207}\text{Pb}/^{206}\text{Pb}$ ratio, with most of the chondrules recording evolved

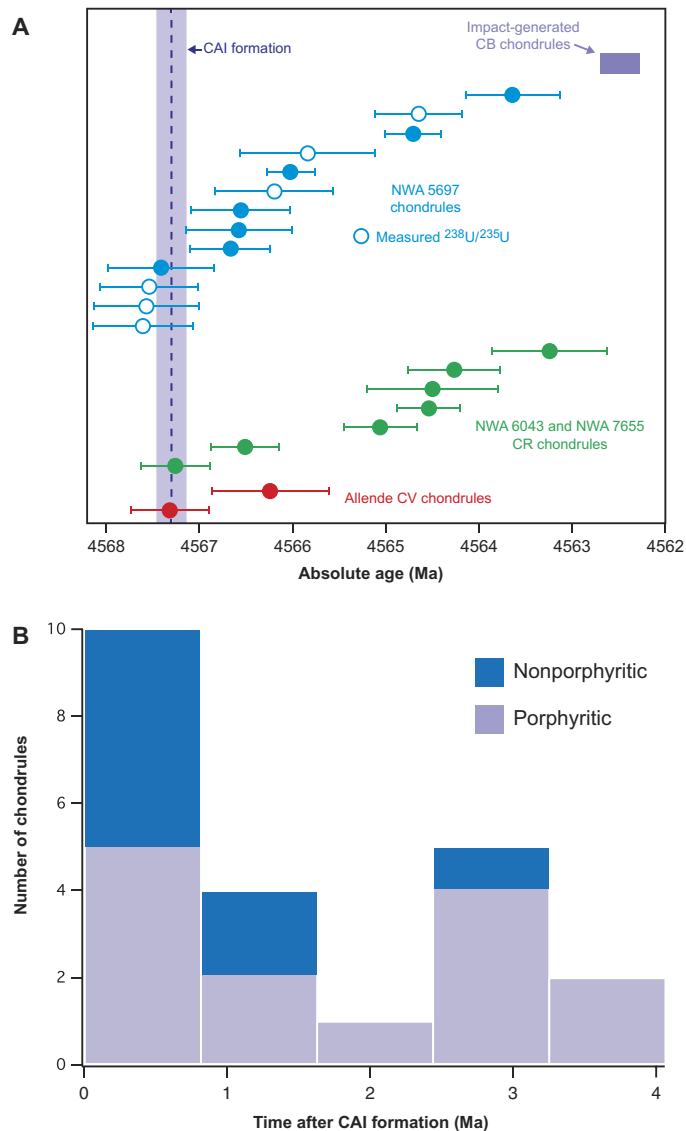

Fig. 1. Absolute chronology of chondrule formation. (A) Pb-Pb dates for individual chondrules from NWA 5697 (L3.10), NWA 6043 (CR2), NWA 7655 (CR2), and Allende (CV3). The Allende chondrules and three chondrules from NWA 5697 were previously reported (6). The timing of CAI formation is accepted to be 4567.30 ± 0.16 Ma (6). The CB chondrules are interpreted as having formed from colliding planetesimals at 4562.49 ± 0.21 Ma (31). (B) Histogram depicting the Pb-Pb age distribution of individual chondrules ($n = 22$) relative to CAI formation. A full description of the methods used to collect the data reported in the paper is available in the Supplementary Materials.

compositions relative to the most primitive composition defined by chondrules 2-C1 and C1. Incorporation of U-rich, refractory material such as CAIs in chondrule precursor could, in principle, produce apparently evolved initial Pb isotope compositions. However, this process would result in correlated variability between the initial Pb isotope compositions and the Al/Mg ratios of the bulk chondrules, which is not observed in our data set (fig. S26). A component of the elevated $^{207}\text{Pb}/^{206}\text{Pb}$ ratio could also reflect mass-dependent heavy isotope enrichment associated with evaporative loss of Pb. To assess this possibility, we have measured the isotope composition of Zn, an element

Fig. 2. Lead isotope evolution diagrams. (A) Initial Pb isotopic compositions of individual chondrules. The initial Pb isotope compositions are defined by the intersection of the individual isochrons and a Pb evolution array anchored on the solar system initial Pb isotope composition defined by chondrules 2-C1 and C1, which record the most primitive initial Pb isotope compositions (see the Supplementary Materials for the calculation of uncertainties on initial Pb isotope compositions). Individual chondrule data points have been displaced to the left- and right-hand side of the solar system initial Pb array for clarity. **(B)** Initial $^{207}\text{Pb}/^{206}\text{Pb}$ compositions and age variation diagram. The $(^{207}\text{Pb}/^{206}\text{Pb})_{\text{initial}}$ values are reported in per 10,000 deviations (ϵ unit) from the composition defined by chondrules 2-C1 and C1. The blue box reflects the range of $\epsilon(^{207}\text{Pb}/^{206}\text{Pb})_{\text{initial}}$ compositions of the >1-My chondrules back-calculated at 4566.8 Ma. The robustness of the $\epsilon(^{207}\text{Pb}/^{206}\text{Pb})_{\text{initial}}$ and age correlation, including the effect of point selection of the individual regressions, has been statistically evaluated using a Monte Carlo approach (see the Supplementary Materials).

with comparable volatility as Pb (18), for seven chondrules. Assuming that the relative difference in the magnitude of the mass-dependent isotope fractionation between Zn and Pb is proportional to $1/m^2$ (19), Zn is predicted to record a level of isotopic fractionation that is ~ 10 times greater than Pb. The $\delta^{66}\text{Zn}$ values for the subset of chon-

drules range from $-0.26 \pm 0.05\text{‰}$ to $-2.20 \pm 0.05\text{‰}$, representing light isotope enrichment that is not expected during simple evaporative loss, which typically results in heavy Zn isotope composition (20). The enrichment of light Zn isotopes in chondrules has been interpreted as reflecting removal of an isotopically heavy phase such as sulfide (21). This process is predicted to occur during remelting events (22), in keeping with the complex thermal reprocessing history inferred here. Regardless of the mechanism governing Zn isotope fractionation, the light and limited variability of Zn isotope fractionation in these chondrules ($\sim 2\text{‰}$) confirms that the range of the $^{207}\text{Pb}/^{206}\text{Pb}$ ($\sim 12\text{‰}$) ratios is not a product of mass-dependent fractionation.

The initial Pb isotope composition of chondrules is positively correlated with their crystallization ages (Fig. 2B). Only chondrules formed in the first million years of the protoplanetary disk record primitive compositions, whereas younger chondrules show progressively more evolved initial Pb isotope compositions. The <1-My chondrule population records variability in the initial Pb isotope compositions, which corresponds to ~ 50 ϵ units in the $^{207}\text{Pb}/^{206}\text{Pb}$ ratio. This range of initial Pb isotope compositions in the old chondrules could reflect the incorporation of radiogenic Pb possibly related to dust condensation following the evaporative melting of CAIs, which can only occur at early times. The progressively more evolved initial Pb isotope compositions and the lack of primitive initial Pb recorded by younger chondrules suggest that these formed from precursors having already accumulated radiogenic Pb, which is indicative of material characterized by an elevated μ value. Apart from the chondrule-forming process, wide-scale planetesimal melting and the production of magma oceans are efficient mechanisms for Pb devolatilization during the lifetime of the protoplanetary disk (23). Thus, it is conceivable that the evolved initial Pb isotope signatures observed in young chondrules reflect the recycling of disrupted planetesimal fragments during chondrule-forming episodes. However, the inferred μ values of differentiated planetesimals, such as the angrite parent body, are, at least, one order of magnitude more extreme than those observed in chondrules, inconsistent with the bulk of the precursor material of young chondrules reflecting disrupted planetesimal fragments. Moreover, the accretion, differentiation, and establishment of long-lived magma oceans leading to planetesimal-scale Pb devolatilization are thought to occur over time scales of ~ 3 to 4 My (24, 25). Given that most of the chondrules reported here have ages within ~ 3 My of solar system formation within analytical uncertainty, this process cannot easily account for the elevated μ values recorded by most chondrules. Thus, we infer that the evolving initial Pb isotope compositions of chondrules during the lifetime of the disk reflect the recycling and, hence, remelting of their precursors during earlier chondrule-forming events. Thermally processed precursors may represent chondrule fragments or, alternatively, entire chondrules having experienced more than one chondrule-forming event.

A prediction of chondrule reworking in a closed system is a progressive increase in the inferred μ values of individual chondrules through time. Although this correlation appears to be present in our data set (fig. S27), a number of different disk processes may perturb this relationship. For example, the chondrule-forming process may have been more efficient (with higher temperatures) at early times such that a progressive decrease in μ values with time would be expected for chondrules formed during the epoch of primary chondrule production, namely, in the first million years. Moreover, the accumulation of small amounts of Pb-rich dust onto the rims of chondrules that may be incorporated into the chondrule interior during flash melting will have

the effect of lowering the μ value, which would prevent the μ value from reaching extreme values in these cases. Hence, it may be significant that the three chondrules projecting to modern terrestrial Pb isotopic compositions (and therefore having an effectively infinite μ value) correspond to older chondrules that may have avoided the reworking and incorporation of Pb-rich dust.

To assess the validity of the proposal that the young, >1-My chondrules with evolved initial Pb isotope compositions reflect the recycling of chondrules formed at early times, we back-calculate the range of initial Pb isotope compositions that correspond to a U/Pb fractionation age of ~500,000 years after CAIs. This age is supported by the age distribution, indicating that the bulk of the chondrules records crystallization ages within the first million years of protoplanetary disk evolution (Fig. 1B). In Fig. 2B, we show the range of initial Pb isotope compositions of the >1-My chondrules back-calculated for a primary U/Pb fractionation age of 4566.8 My, which corresponds to ~50 ϵ units in the $^{207}\text{Pb}/^{206}\text{Pb}$ ratio. This range of initial Pb isotope compositions is comparable to that of chondrules that record crystallization ages <1 My after the solar system formation, consistent with the proposal that the bulk of the young chondrules reflect the recycling of chondrules formed at early times.

DISCUSSION

Absolute and relative chronology of chondrule formation

The absolute ages we report demonstrate that the production and melting of chondrules began contemporaneously with CAI condensation and melting and continued for ~4 My. Apart from Pb-Pb dating, the only other method that has been used to provide insights into the timing of crystallization of individual chondrules via the internal isochron approach is the short-lived ($T_{1/2} \approx 0.7$ My) ^{26}Al - ^{26}Mg decay system. Unlike the assumption-free U-corrected Pb-Pb dating method, the validity of ^{26}Al - ^{26}Mg relative ages is based on the hypothesis that the $^{26}\text{Al}/^{27}\text{Al}$ ratio was homogeneous in the solar protoplanetary disk with an initial value of $\sim 5 \times 10^{-5}$ at the time of CAI formation. Attempts to provide a chronology of chondrule formation based on the short-lived ^{26}Al - ^{26}Mg system infer that chondrule formation began ~2 to 3 My after CAI condensation and melting (26). This apparent age difference, dubbed the CAI-chondrule age gap, has been used to constrain mechanisms of chondrule formation (27). We discuss below the possible explanations for the inconsistency between ages of individual chondrules derived by the Al-Mg and U-Pb systems.

One possible explanation for the age discordance is that the age variability or, alternatively, the preponderance of old ages inferred from Pb-Pb dating is an artifact of the progressive step-leaching dissolution technique used here, relative to more traditional approaches based on the analyses of separated mineral phases. However, three lines of evidence suggest that this is not the case. First, two independent estimates of the Pb-Pb age for the SAH99555 angrite using the step-leaching dissolution technique (28) and a more traditional mineral separation approach (29) yield ages that are concordant within $280,000 \pm 405,000$ years. Similarly, independent estimates for the timing of condensation of CAIs using different techniques (6, 30) define ages that are within $140,000 \pm 505,000$ years. In both cases, the potential offset between the two techniques is well within the typical uncertainties of the chondrule ages reported here. Finally, using the step-leaching dissolution technique, Bollard *et al.* (31) report Pb-Pb ages for four individual chondrules from the Gujba metal-rich chondrite that are identical within 340,000 years. This chondrite is thought

to have formed from a vapor-melt plume produced by a giant impact between planetary embryos, resulting in coeval ages of its various components (32). Collectively, these observations suggest that the Pb-Pb dates reported here for chondrules are accurate to within their stated uncertainties.

If the Pb-Pb dates are accurate, a likely explanation for the age mismatch between the absolute and relative ages is that the assumption of homogeneous initial disk $^{26}\text{Al}/^{27}\text{Al}$ composition that underpins the validity of ^{26}Al - ^{26}Mg ages is incorrect. A number of recent studies have suggested a reduced initial $^{26}\text{Al}/^{27}\text{Al}$ value in solids that accreted to form protoplanets (33, 34), which would translate into younger ^{26}Al - ^{26}Mg ages relative to the Pb-Pb dates. The bulk of the Pb-Pb ages reported here are from the NWA 5697 ordinary chondrite, as well as various CR chondrites. In Fig. 3, we show the age distribution of NWA 5697 chondrules inferred from Pb-Pb dating relative to the ^{26}Al - ^{26}Mg ages of chondrules from the most primitive ordinary chondrites, assuming that the initial inner disk $^{26}\text{Al}/^{27}\text{Al}$ inventory was $\sim 1.5 \times 10^{-5}$ (33). Under this assumption, the two dating methods return comparable age distributions, consistent with the hypothesis of a reduced inner disk ^{26}Al inventory relative to the canonical abundance. However, the post-2-My age distribution inferred from the ^{26}Al - ^{26}Mg system is difficult to characterize using existing data, given the low $^{26}\text{Al}/^{27}\text{Al}$ abundance of $< 2 \times 10^{-6}$ at that time. We note that preliminary results reporting the ^{26}Al - ^{26}Mg and Pb-Pb ages of the same individual chondrules are consistent with the proposal of a reduced inner disk ^{26}Al inventory (35, 36).

Finally, it has been recently suggested that metal-rich chondrites, including CR chondrules, formed from an ^{26}Al -poor reservoir possibly located beyond the orbits of the gas giant planets (37, 38). In detail, it is proposed that the $^{26}\text{Mg}^*$ and ^{54}Cr compositions of CR chondrules require significant amounts (25 to 50%) of primordial ^{26}Al -free molecular cloud matter in their precursor material. Accepting that the true age distribution of CR chondrules is reflected by their Pb-Pb systematics, a prediction of this model is that individual CR chondrules will record the lowest initial $^{26}\text{Al}/^{27}\text{Al}$ values relative to other chondrite groups and that a significant number of objects will lack evidence for live ^{26}Al if these formed >1 My after CAI condensation. These predictions are in line with the recent ^{26}Al - ^{26}Mg systematics of CR chondrules, which record initial $^{26}\text{Al}/^{27}\text{Al}$ values of typically less than 3×10^{-6} and more than 50% of the objects investigated having no sign for live ^{26}Al at the time of their crystallization (39, 40). These observations, together with the clear evidence for ^{26}Al heterogeneity at the time of CAI formation (41), emphasize that the ^{26}Al - ^{26}Mg system may not provide an accurate chronology of chondrule formation and, hence, disk processes.

Dynamical evolution of the solar protoplanetary disk

In contrast to the nonigneous CAIs that formed as fine-grained condensates near the protosun in a brief time interval associated with collapse of the presolar molecular cloud core, most of the chondrules are thought to be products of flash heating of dust aggregates in different disk regions, possibly by shock wave heating (42). Because shocks require the existence of a gaseous disk, our chondrule Pb-Pb dates allow us to provide constraints on the lifetime of the solar protoplanetary disk, including the timing of its establishment relative to the protosun, if these objects are formed by shock wave heating. Six chondrules (5-C1, 2-C1, 5-C2, 5-C10, 1-C1, and C30) have ages identical to those of CAIs within analytical uncertainty, defining a population with a weighted mean age of 4567.41 ± 0.19 Ma. Both astronomical

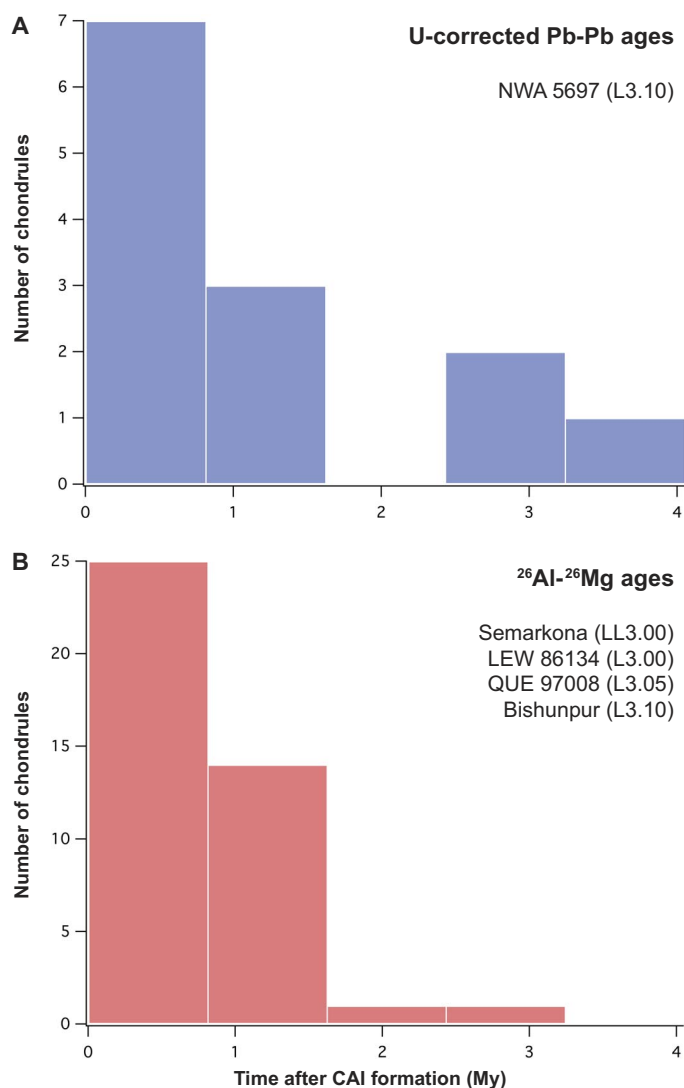

Fig. 3. Histograms depicting the absolute and relative timing ages of chondrules from unequilibrated ordinary chondrites of low petrologic type (≤ 3.1) based on internal isochron relationships. (A) Pb-Pb dates of chondrules from the NWA 5697 ordinary chondrite (this study). (B) ^{26}Al - ^{26}Mg ages of chondrules from Semarkona, LEW 86134, QUE 97008, and Bishunpur ordinary chondrites (65–68). The relative ^{26}Al - ^{26}Mg ages are calculated, assuming that the precursor material from which these chondrules formed had a reduced initial $^{26}\text{Al}/^{27}\text{Al}$ value corresponding to $\sim 1.5 \times 10^{-5}$ (33). Three chondrules record initial $^{26}\text{Al}/^{27}\text{Al}$ slightly higher than 1.5×10^{-5} but are within the analytical uncertainty of this estimate and, hence, have been assigned a $T = 0$ formation age for simplicity.

observations and numerical simulations suggest that protoplanetary disks formed shortly after star formation, namely, during the deeply embedded stage (43, 44). The age uncertainty associated with the ancient chondrule population indicates that these objects formed at most $\sim 138,000$ years after CAIs. Thus, this time scale defines an upper limit for the establishment of the protoplanetary disk formation after CAI formation and, by extension, the collapse of the protosun. From an astronomical perspective, this time corresponds to the earliest deeply embedded stage (class 0) of protostar evolution. It is well established that the disk was largely dissipated (45) at the time of formation of the impact-generated chondrules from the Gujba metal-rich chondrite at

4562.49 ± 0.21 Ma (31). Using the age of the youngest chondrule identified here, we define minimum and maximum lifetimes of ~ 3.3 and ~ 4.5 My, respectively, for the active phase of the solar protoplanetary disk. These new time scales for the establishment and lifetime of the solar protoplanetary disk are in keeping with astronomical observations of young stars and their disks (46) and indicate that the formation of a disk amiable to the production of asteroidal bodies and planetary embryos occurred shortly after the collapse of the protosun.

Our data and interpretation provide insights into the accretion history and thermal processing of dust in the protoplanetary disk. In the early stages of low-mass star formation, mass accretion to the protostar occurs from the surrounding envelope via a circumstellar disk structure (47). This represents the deeply embedded phase of star formation that only lasts for a small fraction of a disk lifetime, typically ~ 0.5 My compared to several million years. During this epoch, fresh, volatile-rich envelope material is processed through the disk and thus available to participate in the formation of early solar system solids. Chondrules formed within the first ~ 1 My of the disk lifetime have primitive initial Pb isotope compositions that are consistent with incorporation of thermally unprocessed material characterized by a solar μ value. In contrast, chondrules formed at later times record evolved compositions, which require limited or no admixing of primordial dust with a solar μ value to their precursors. We infer that this reflects the transition between two distinct accretionary regimes during the early evolution of the solar protoplanetary disk. The first ~ 1 My reflects the main epoch of accretion and thermal processing of envelope material to the disk, which represents the regime of primary production of chondrules. Hence, we suggest that the bulk of the chondrules preserved in chondrite meteorites were originally produced during this period. In contrast, the >1 -My regime represents an epoch dominated by the transport and recycling of chondrules, including the remelting of the first-generation chondrules. The limited evidence for the admixing of primordial dust with a solar μ value in >1 -My chondrules indicates that the envelope of accreting material surrounding the protosun had largely dissipated by that time.

Chondrule formation and recycling mechanisms

On the basis of petrographic, mineralogical, and chemical observations, it is thought that chondrules formed by the melting of isotopically diverse solid precursors in the dust-rich regions of the protoplanetary disk during repeatable and localized transient heating events (27). The inferred thermal histories of chondrules, as well as the high solid densities (48) required for their formation, are consistent with shock wave heating as the primary source of energy for the thermal processing and melting of chondrule precursors. Recent magnesium and chromium isotope systematics of CR chondrules suggest that these objects formed in a reservoir distinct from other chondrite groups possibly located beyond the orbits of the gas giant planets (37, 38). These data require a heat source that enables the production of chondrules at a wide range of orbital distances. A number of mechanisms have been proposed for producing chondrule-like objects in gaseous disks, including shocks produced by disk gravitational instability (49, 50) as well as eccentrically orbiting planetesimals and planetary embryos (51–53). The Pb isotope systematics of individual chondrules reported here suggest that the primary chondrule production was limited to <1 My of the protoplanetary disk evolution, namely, during the deeply embedded stage of the protosun characterized by significant accretion of envelope material to the disk. The most efficient source of shocks during this epoch is shock fronts associated

with spiral arms generated in a gravitationally unstable disk (50, 54). Numerical simulations indicate that this type of instability occurs in early-formed disks that are relatively massive compared to their host stars ($M_d/M_* \geq 0.1$) (55). Shocks generated in this regime are modeled to be highly efficient in the inner disk region and possibly extend to ~ 10 astronomical units (50, 56), thereby providing a possible mechanism for the thermal processing of disk solids in early times on a global scale. However, because accretion to the disk decreases and the envelope dissipates, the resulting disk mass at later times is thought to be far too low to sustain gravitational instabilities. Thus, a distinct source of shocks is required for the remelting and, hence, recycling of the chondrules from ~ 1 to ~ 4 My after the collapse of the protosun. The accretion of large planetesimals and Mars-sized planetary embryos is believed to occur over time scales of ~ 0.5 to ~ 3 My (24, 33, 57), comparable to the lifetime of the protoplanetary disk inferred from our chondrule Pb-Pb dates. Hence, bow shocks resulting from planetesimals and planetary embryos traveling on eccentric orbits provide a possible source of heating for the thermal processing of solids in the >1 -My regime. Thus, it is apparent that different sources of heating are required to satisfy the Pb-Pb isotopic ages of individual chondrules, suggesting a multiplicity of chondrule-forming and remelting mechanisms. However, the higher proportion of <1 -My chondrules with nonporphyritic textures (Fig. 1B), which indicates complete melting at higher temperatures, suggests that the chondrule-forming process was more efficient during early times.

The age variability recorded by individual chondrules establishes the existence of multiple generations of high-temperature solids within individual chondrite groups. This observation is in keeping with the existence of isotopic heterogeneity between chondrules from a single chondrite for nuclides such as ^{54}Cr and ^{50}Ti , which track genetic relationships between the silicate precursors of solids, asteroids, and planetary bodies (37, 38, 58). Collectively, these data require that chondrule formation, recycling, and outward mass transport occurred during the lifetime of the protoplanetary disk. Outward transport of chondrules could have occurred by a variety of time-dependent processes, including turbulent diffusion (59) and stellar outflows (60).

The observed chondrule age range does not support the concept that chondrules and matrix in a single chondrite group are genetically related, which is based on an apparent chemical complementarity between chondrules and coexisting matrix (61). However, recent models of evolving viscous disks suggest that a complementary relationship between chondrules and dust can be preserved for long time scales provided that the decoupling between chondrules and gas is limited (62). In these models, various chondrule populations remained in complementarity such that the bulk contribution from each source is chemically solar and, thus, so is the final mixture. Alternatively, the observed chondrule-matrix complementarity may be an expression of the generic process of chondrule formation and does not reflect a genetic link (38). In this view, the matrix comprises a complement related to the chondrule formation process such that the bulk composition of the matrix is shifted from its starting composition and thus appears complementary to a chondrule composition. This does not require that the matrix is genetically linked to the chondrules in an individual chondrite but merely that some of it has experienced earlier chondrule formation events. Thus, fractions of the matrix in a particular chondrite may be complementary to chondrule populations in other chondritic meteorites. Likewise, the apparent isotopic complementarity for siderophile elements, such as W and Mo (63, 64), between chondrules and matrix may reflect the selective destruction and/or removal of isotopically anomalous metal phases during chondrule formation.

Finally, the efficient production of chondrule at early times and their continuous recycling inferred from our Pb isotope data are consistent with the proposal that chondrules may promote the growth of asteroidal bodies and planetary embryos by chondrule accretion (5). Chondrite meteorites are traditionally used to estimate the composition of the material that accreted to form the Earth. However, our results suggest that chondrules may be the dominant component controlling the composition of planetary bodies. Thus, a better understanding of the bulk elemental composition of these objects, including their volatile element inventory, may provide insights into the nature of the material precursor to terrestrial planets in our solar system and abroad.

MATERIALS AND METHODS

Following the identification of chondrules of suitable sizes from ~ 1 -mm-thick slabs of the NWA 5697, NWA 7655, and NWA 6043 meteorites, chondrules selected for isotopic investigations were characterized for their petrology and mineral chemistry using a scanning electron microscope and electron microprobe at the University of Copenhagen. Chondrules were liberated from the meteorite slabs using a variable-speed Dremel fitted with either cone-shaped, diamond-coated cutting tool or dental drill bits and broken in fragments using an agate mortar and pestle. After sequential dissolution and chemical purification, the Pb isotope composition of each aliquot was determined using a Thermo Fisher Triton TIMS at the Centre for Star and Planet Formation based on protocols described by Connelly *et al.* (6) and Bollard *et al.* (31). We determined the Pb isotope composition of the individual phases of chondrules 1-C2 and 3-C1 using a CAMECA 1280 ion microprobe (IMP) at the Swedish Museum of Natural History. The U isotope compositions of an aliquot of the chondrules used for Pb-Pb dating were determined for seven chondrules using the Thermo Fisher Neptune Plus MC-ICPMS at the Centre for Star and Planet Formation based on protocols described by Connelly *et al.* (6). Similarly, the Zn isotope compositions of an aliquot of the material used for Pb-Pb dating were determined for seven chondrules using the Thermo Fisher Neptune Plus at the Institut de Physique du Globe de Paris based on protocols described by Pringle *et al.* (21).

Acknowledgments: We thank S. Krot and L. Buchhave for the discussion on various aspects of this study. **Funding:** This study was funded by grants from the Danish National Research Foundation (#DNRF97) and the European Research Council (Consolidator grant agreement 616027-Stardust2Asteroids to M.B.). **Author contributions:** M.B. and J.N.C. designed the research. J.B., J.N.C., M.J.W., E.A.P., L.B., F.M., and M.B. performed the research. J.B., J.N.C., M.J.W., E.A.P., L.B., J.K.J., Å.N., F.M., and M.B. analyzed the data. M.B., J.B., and J.N.C. wrote the manuscript. **Competing interests:** The authors declare that they have no competing interests. **Data and materials availability:** All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors. This is publication 515 of the Nordsim facility.
