

## ELECTROCHEMISTRY

Combining scaling relationships overcomes rate versus overpotential trade-offs in O<sub>2</sub> molecular electrocatalysis

Daniel J. Martin, Brandon Q. Mercado, James M. Mayer\*

The development of advanced chemical-to-electrical energy conversions requires fast and efficient electrocatalysis of multielectron/multiproton reactions, such as the oxygen reduction reaction (ORR). Using molecular catalysts, correlations between the reaction rate and energy efficiency have recently been identified. Improved catalysis requires circumventing the rate versus overpotential trade-offs implied by such “scaling relationships.” Described here is an ORR system—using a soluble iron porphyrin and weak acids—with the best reported combination of rate and efficiency for a soluble ORR catalyst. This advance is achieved not by “breaking” scaling relationships but rather by combining two of them. Key to this behavior is a polycationic ligand, which enhances anionic ligand binding and changes the catalyst  $E_{1/2}$ . These results show how combining scaling relationships is a powerful way toward improved electrocatalysis.

## INTRODUCTION

Improving the rates and efficiencies of electrocatalytic reactions is critical to the development of chemical-to-electrical energy conversion technologies. The oxygen reduction reaction (ORR)—the combination of dioxygen (O<sub>2</sub>), protons, and electrons to give water—is an important example common to fuel cells (1, 2). Because current ORR technologies use platinum catalysts, current research seeks replacements sourced from earth-abundant materials (3). One approach to developing catalytic systems with high rates [turnover frequencies (TOFs)] and high efficiencies (low overpotentials,  $\eta$ ) has been the development of scaling relationships. The properties of heterogeneous electrocatalysts can often be understood and even predicted using a single scaling descriptor, typically the energy of substrate binding to the catalyst surface (4). In contrast, soluble molecular electrocatalysts, which can be studied in more atomistic and mechanistic detail, follow multiple kinetic/thermodynamic scaling relationships (5). These describe how the maximum TOFs [ $\log(\text{TOF}_{\text{max}})$ ] scale with the various terms contributing to the effective overpotential ( $\eta_{\text{eff}}$ ) (5–8) (see the Supplementary Materials). To date, the reported  $\log(\text{TOF}_{\text{max}})/\eta_{\text{eff}}$  relationships always describe a trade-off: Faster catalysis is only achieved at lower efficiencies (higher  $\eta_{\text{eff}}$ ).

We report here an inverse scaling relationship, one that allows for faster rates at higher efficiencies, using a polycationic iron porphyrin catalyst with buffered weak acids in acetonitrile (MeCN) (Fig. 1A). With acetic acid/acetate buffer (AcOH/AcO<sup>−</sup>), this system achieves a  $\text{TOF}_{\text{max}}$  of 170 s<sup>−1</sup> at 0.54 V  $\eta_{\text{eff}}$ , which is  $\sim 10^4$  faster than any previously reported molecular ORR catalyst at this  $\eta_{\text{eff}}$  (2, 9). As described below, this unprecedented result is predictable by combining two kinetic/thermodynamic scaling relationships. The coupling of the two scaling relationships is a result of the electrostatic ligand design of **1** that enables cooperativity between the catalyst and buffer.

## RESULTS

Iron  $\alpha\beta\alpha\beta$ -*tetra(o-N,N',N''-trimethylanilinium)porphyrin* (**1**) was prepared as reported (10) and was isolated and characterized as the di-aquo, penta-triflate salt of the  $\alpha\beta\alpha\beta$  isomer by single-crystal x-ray

diffraction (Fig. 1C). Cyclic voltammograms (CVs) of **1** in MeCN containing 0.1 M tetra-*n*-butylammonium tetrafluoroborate electrolyte ([*n*-Bu<sub>4</sub>N][BF<sub>4</sub>]) showed three reversible redox features (Fe<sup>III/II</sup>, Fe<sup>III/I</sup>, and Fe<sup>I/0</sup>) (10). Solutions containing **1**, O<sub>2</sub>, and buffered acid (1:1 [HA]/[A<sup>−</sup>]) showed a large, irreversible current at the Fe<sup>III/Fe<sup>II</sup></sup> reduction potential, indicative of catalysis (5, 7, 11). All CV experiments were buffered (1:1 acid-to-conjugate base) to define the ORR equilibrium potential and  $\eta_{\text{eff}}$ , which was calculated using Eq. 1 (5, 7, 11).

Measurements of the H<sub>2</sub>O/H<sub>2</sub>O<sub>2</sub> selectivity were performed using rotating ring disk electrochemistry (RRDE). In all cases, electrocatalysis was found to give <20% H<sub>2</sub>O<sub>2</sub> (see the Supplementary Materials). This high selectivity for H<sub>2</sub>O is similar to other iron porphyrin catalysts under comparable conditions (5, 7, 11). With AcOH/AcO<sup>−</sup> buffer, catalysis occurs at potentials below the equilibrium potential for O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub> and thus requires thermodynamic selectivity for H<sub>2</sub>O [cf., (9)].

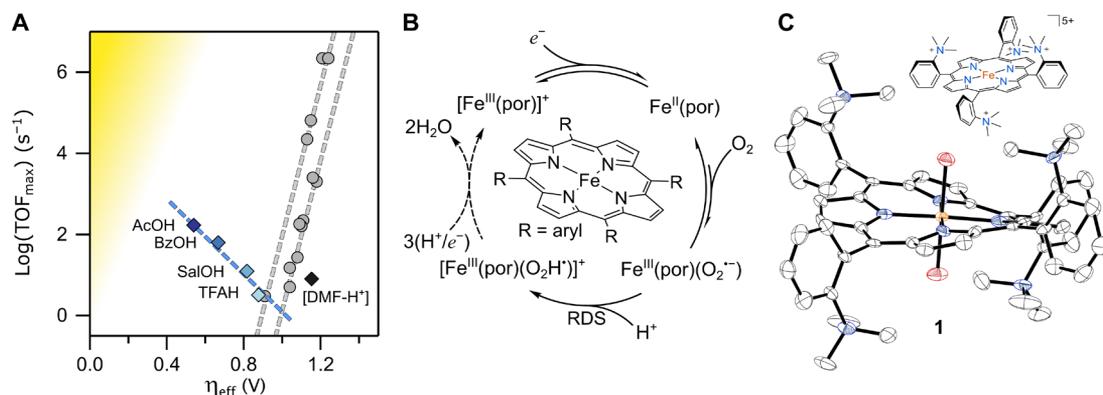

TOF<sub>max</sub> values were determined from the catalytic CVs by foot-of-the-wave analysis (FOWA), Eq. 2 [Table 1; (5, 11, 12)]. This widely used approach normalizes the catalytic currents ( $i_c$ ) to the noncatalytic peak current of the Fe<sup>III/II</sup> couple ( $i_p$ ) at potentials ( $E$ ) near the onset of the catalytic wave, where complications such as substrate depletion are minimized. Given the high selectivity for H<sub>2</sub>O,  $n_{\text{cat}}$  was taken to be 4 (electrons per O<sub>2</sub> reduced), and the conservative  $\sigma = 1$  value was used (see the Supplementary Materials). Measuring TOF<sub>max</sub> values under different conditions showed that the catalytic rate law was first order in [**1**],  $P_{\text{O}_2}$ , and [HA], similar to other Fe(por) catalysts (5, 7, 11). [HA] is the concentration of free acid after considering homoconjugation (see the Supplementary Materials). These results implicate a catalytic mechanism of (i) initial reduction of [Fe<sup>III</sup>(por)]<sup>+</sup> to Fe<sup>II</sup>(por), (ii) pre-equilibrium O<sub>2</sub> binding to form the superoxide complex, Fe<sup>III</sup>(por)(O<sub>2</sub><sup>•−</sup>), and (iii) rate-limiting proton transfer to form [Fe<sup>III</sup>(por)(O<sub>2</sub>H<sup>•</sup>)]<sup>+</sup> (Fig. 1B). Experimental and computational studies of this mechanism are reported in (5, 11, 12).

$$\eta_{\text{eff}} = E_{\text{ORR}}^0 - E_{1/2} - \frac{2.303RT}{n_{\text{cat}}F} \log \left( \frac{[\text{H}_2\text{O}]^2 [\text{A}^-]^4}{P_{\text{O}_2} [\text{HA}]^4} \right) - (0.0592\text{V}) p K_a \quad (1)$$

$$\frac{i_c}{i_p} = \frac{2.24 n_{\text{cat}}^\sigma \sqrt{\frac{RT}{Fv} \text{TOF}_{\text{max}}}}{1 + \exp \left[ \frac{F}{RT} (E - E_{1/2}) \right]} \quad (2)$$

<sup>†</sup> $E_{1/2}(\text{Fe}^{\text{III/II}})$  reduction potential (versus ferrocenium/ferrocene, under Ar, with 100 mM buffer).

<sup>‡</sup>From Eq. 2;  $\pm 0.02$  V.

ORR catalysis was studied in MeCN using **1** and a series of buffers. Using  $N,N'$ -dimethylformamidium triflate ( $[\text{DMF-H}^+]\text{OTf}$ ;  $\text{p}K_{\text{a}}=6.1$ , where  $K_{\text{a}}$  is the acid dissociation constant),  $\text{TOF}_{\max}=8.5\text{ s}^{-1}$  and  $\eta_{\text{eff}}=1.16\text{ V}$  (Table 1). Within the  $\log(\text{TOF}_{\max})/\eta_{\text{eff}}$  space, this  $[\eta_{\text{eff}}, \log(\text{TOF}_{\max})]$  data point roughly fits the scaling relationships previously reported for  $\text{Fe}(\text{por})$  electrocatalysts under similar conditions (Fig. 1A, black diamond) (5). In contrast, using acetic acid (AcOH,  $\text{p}K_{\text{a}}=23.5$ ) gave markedly improved catalysis: a faster  $\text{TOF}_{\max}$  ( $170\text{ s}^{-1}$ ) at less than half the  $\eta_{\text{eff}}$  (0.54 V). This result contradicts previously derived  $\log(\text{TOF}_{\max})/\eta_{\text{eff}}$  relationships, which always predict that a lower overpotential will give a slower rate, as seen for iron tetra-arylporphyrins (see the Supplementary Materials) (7). Catalysis with **1** and trifluoroacetic acid (TFAH), salicylic acid (SalOH), or benzoic acid (BzOH) similarly show improvements in both  $\text{TOF}_{\max}$  and  $\eta_{\text{eff}}$  versus the  $[\text{DMF-H}^+]$  point (Fig. 1, blue diamonds, and Table 1). Together, the carboxylic acid  $[\eta_{\text{eff}}, \log(\text{TOF}_{\max})]$  points define an unexpected inverse  $\log(\text{TOF}_{\max})/\eta_{\text{eff}}$  relationship (Fig. 1A, blue dashed line), a previously unrealized goal in molecular electrocatalysis (5, 13, 14). The following sections describe a model that explains this inverse relationship as the sum of two known kinetic/thermodynamic scaling relationships (7).

## DISCUSSION

Catalyst **1** is unique among the  $\text{Fe}(\text{por})$  series because changing the buffer notably affects two properties of the catalytic system: the acid  $\text{p}K_{\text{a}}$  and also the catalyst  $E_{1/2}$ , due to carboxylate binding. Since both  $\text{p}K_{\text{a}}$  and  $E_{1/2}$  each modulate the  $\text{TOF}_{\max}$  and  $\eta_{\text{eff}}$  in different ways [see the Supplementary Materials and (5, 7) for further discussion], a single scaling relationship is not adequate for predicting the composite changes in  $\log(\text{TOF}_{\max})/\eta_{\text{eff}}$ . Instead, the scaling relationships—which only establish directionality within the  $\log(\text{TOF}_{\max})/\eta_{\text{eff}}$  space—must be recast as vectors. Vectors have directionality and length and are additive.

The Nernst equation for this ORR reaction (Eq. 1) shows that a one-unit increase in acid  $\text{p}K_{\text{a}}$  decreases  $\eta_{\text{eff}}$  by 0.059 V:  $\Delta\eta_{\text{eff}}=-0.059\text{ V})\Delta\text{p}K_{\text{a}}$  (15, 16). In iron porphyrin ORR catalysis, protonation is the rate-determining step, and the  $\text{TOF}_{\max}$  varies with  $\text{p}K_{\text{a}}$  according to the Bronsted equation:  $\Delta\log(\text{TOF}_{\max})=-\alpha(\Delta\text{p}K_{\text{a}})$ , where  $\alpha\approx 0.3$  (5, 7, 11). For the range of carboxylate buffers used here, TFAH/TFA<sup>–</sup> to AcOH/AcO<sup>–</sup>, the change in  $\text{p}K_{\text{a}}$  is 10.9. Therefore, with  $\alpha=0.3$  and holding all other properties constant, the changes in  $\eta_{\text{eff}}$  and  $\log(\text{TOF}_{\max})$  associated with the 10.9  $\text{p}K_{\text{a}}$  shift can be

described as the vector  $\vec{v}_{pK_a}$  in the  $[\eta_{\text{eff}}, \log(\text{TOF}_{\text{max}})]$  space (Eq. 3, dec stands for decade in  $\text{TOF}_{\text{max}}$ ; Fig. 3).

$$\vec{v}_{pK_a} = \langle \Delta \eta_{\text{eff}}, \Delta \log(\text{TOF}_{\text{max}}) \rangle = \langle -0.059(\Delta pK_a), -\alpha(\Delta pK_a) \rangle = \langle -0.64 \text{ V}, -3.3 \text{ dec} \rangle \quad (3)$$

In addition to acid  $pK_a$ , the buffer identity also affects the  $E_{1/2}$ . When buffered carboxylic acids are titrated into solutions of **1**, the catalyst  $E_{1/2}$  shifts negatively, by as much as 350 mV (Fig. 2A). This shift results from the conjugate base of the buffer (e.g., acetate) binding more strongly to the  $\text{Fe}^{\text{III}}$  versus the  $\text{Fe}^{\text{II}}$  form of **1**. This behavior was documented and explained many years ago for chloride binding to iron tetraphenylporphyrin (17). At 0.1 M carboxylate buffer, the  $E_{1/2}$  values vary linearly with acid  $pK_a$  ( $-28 \pm 1 \text{ mV}/pK_a$ ; Fig. 2B). In contrast, buffers with cationic acids and neutral conjugate bases ( $[\text{DMF-H}^+]/\text{DMF}$  and  $[\text{Lut-H}^+]/\text{Lut}$ ) give only small shifts in  $E_{1/2}$  ( $< 50 \text{ mV}$ ; Fig. 2B). This unique distinction is due to the highly cationic nature of **1**, which enhances binding of anionic conjugate bases but not neutral ones (see the Supplementary Materials). Further supporting the importance of the cationic ligand, no notable change in catalyst  $E_{1/2}$  was reported when iron tetraphenylporphyrin—an analog without the cationic trimethylanilinium groups—was combined with similar buffers under similar conditions (7).

Changes in  $E_{1/2}$  also affect  $\eta_{\text{eff}}$ :  $\Delta \eta_{\text{eff}} = -\Delta E_{1/2}$  (Eq. 2) (5, 7, 18). For the  $\text{Fe}(\text{por})$  series,  $\log(\text{TOF}_{\text{max}})$  has empirically been shown to change according to  $\log(\text{TOF}_{\text{max}}) = -18.5 \text{ decade}/E_{1/2}(\text{V})$  (see the Supplementary Materials for further discussion) (7). Conceptually, this is because catalysts with more negative  $E_{1/2}$ s (and thus higher  $\eta_{\text{eff}}$ s) bind  $\text{O}_2$  more strongly and form more basic superoxide

complexes, both of which lead to higher  $\text{TOF}_{\text{max}}$  (5). As above, a vector  $\vec{v}_{E_{1/2}}$  can be used to represent the  $\log(\text{TOF}_{\text{max}})/E_{1/2}$  scaling relation and the 0.302 V change in  $E_{1/2}$  upon replacing TFAH/TFA<sup>-</sup> with AcOH/AcO<sup>-</sup> (Eq. 4 and Fig. 3)

$$\begin{aligned} \vec{v}_{E_{1/2}} &= \langle \Delta \eta_{\text{eff}}, \Delta \log(\text{TOF}_{\text{max}}) \rangle \\ &= \langle -\Delta E_{1/2}, -18.5(\Delta E_{1/2}) \rangle \\ &= \langle 0.30 \text{ V}, 5.6 \text{ dec} \rangle \end{aligned} \quad (4)$$

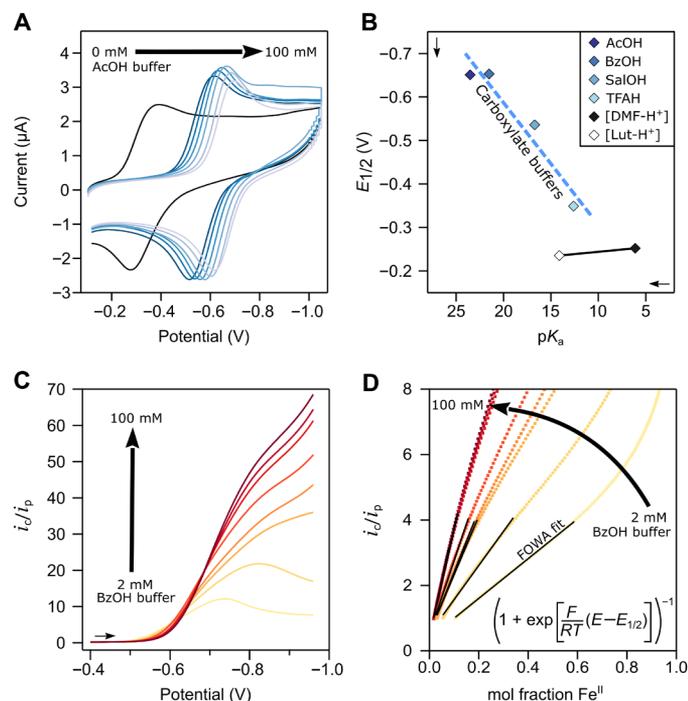

Because the buffer affects both the acid  $pK_a$  and catalyst  $E_{1/2}$ , both  $\vec{v}_{pK_a}$  and  $\vec{v}_{E_{1/2}}$  are needed to describe the changes in  $\eta_{\text{eff}}$  and  $\log(\text{TOF}_{\text{max}})$ . The effects of these changes are additive, described by the vector sum:  $\vec{v}_{\text{sum}} = \vec{v}_{pK_a} + \vec{v}_{E_{1/2}}$  (Eq 5 and Fig. 3). While neither  $\vec{v}_{pK_a}$  nor  $\vec{v}_{E_{1/2}}$  alone fits the observed changes in  $\log(\text{TOF}_{\text{max}})/\eta_{\text{eff}}$ ,  $\vec{v}_{\text{sum}}$  predicts both the directionality and distance from the experimental TFAH coordinate to the AcOH coordinate—within a factor of 3 in  $\text{TOF}_{\text{max}}$ .

$$\vec{v}_{\text{sum}} = \vec{v}_{pK_a} + \vec{v}_{E_{1/2}} = \langle -0.34 \text{ V}, 2.3 \text{ dec} \rangle \quad (5)$$

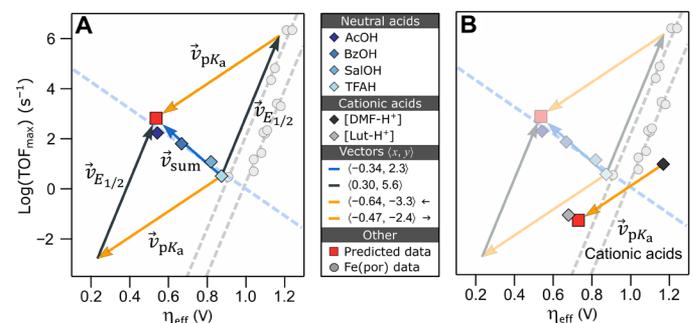

Qualitatively, using a less acidic buffer improves the overall catalysis because of two factors. The change in  $E_{1/2}$  causes a large gain in  $\text{TOF}_{\text{max}}$  at relatively little cost to  $\eta_{\text{eff}}$  (a steep scaling slope). In contrast, the concomitant changes in  $pK_a$  decrease  $\eta_{\text{eff}}$  substantially with only small losses in  $\text{TOF}_{\text{max}}$  (a shallow slope). The combination is a faster  $\text{TOF}_{\text{max}}$  at lower  $\eta_{\text{eff}}$ .

While  $\vec{v}_{\text{sum}}$  is required to analyze the carboxylate buffer data, only  $\vec{v}_{pK_a}$  is needed to predict the change in  $\log(\text{TOF}_{\text{max}})/\eta_{\text{eff}}$  for the cationic buffers (e.g.,  $[\text{DMF-H}^+]/\text{DMF}$  and  $[\text{Lut-H}^+]/\text{Lut}$ ) (Fig. 3B). This is because the change in cationic buffers affects primarily the  $pK_a$ , with little effect on the  $E_{1/2}$ . The lack of change in  $E_{1/2}$  highlights the key role of the cationic macrocycle, which enhances anion binding but not binding of a neutral ligand. Unlike  $\text{CO}_2$  electroreduction by catalyst **1** (10), the remarkable  $\log(\text{TOF}_{\text{max}})/\eta_{\text{eff}}$  data reported here are not just a feature of the catalyst but rather the combination of the catalyst and buffer.

The summative or “tandem” scaling relationship approach developed here is unexpectedly accurate given that the contributing scaling relationships were obtained for a somewhat different set of catalysts, iron porphyrins with different meso-aryl substituents. Yet,

**Fig. 2. Electrochemical studies of **1** under noncatalytic and catalytic conditions.** (A) CVs of **1** showing the shift of  $E_{1/2}$  with increasing concentrations of 1:1 AcOH/AcO<sup>-</sup> buffer. (B) Plot of  $E_{1/2}$  versus the acid  $pK_a$  at 0.1 M buffer. (C) Linear sweep voltammograms under catalytic conditions with different BzOH buffer concentrations. (D) FOWA for voltammograms in (C), with fits between  $i_c/i_p = 1$  to 4.

**Fig. 3. Vector analysis to predict the inverse scaling relationship for **1**.** Predicted coordinates using the vectors are shown as red squares. (A) Plot of  $\log(\text{TOF}_{\text{max}})$  versus  $\eta_{\text{eff}}$  for catalytic systems of **1** and varying carboxylic acid buffers (data points match those in Fig. 1). Superimposed vectors (gold, black, and blue) show predicted changes caused by  $pK_a$ ,  $E_{1/2}$ , and summative effects, respectively. (B) Buffers with cationic acids follow only the  $pK_a$  vector (gold). Prior  $\text{Fe}(\text{por})$  data and  $E_{1/2}$  scaling relationships (7) are included for reference (gray). Uncertainties are smaller than the data points.

these scaling relationships quantitatively hold for the different axial ligands in the **1** + buffer systems examined here. Paradoxically, the tandem approach circumvents the limitations implied by prior molecular scaling relationships—that there is always a trade-off between  $\text{TOF}_{\text{max}}$  and  $\eta_{\text{eff}}$ —because of the robustness and generality of the same “limiting” relationships.

Here, we show that kinetic/thermodynamic scaling relationships for molecular electrocatalysts can be additive and that this tandem scaling approach is a powerful and predictive way to improve multistep electrocatalytic processes. Specifically, summing multiple known scaling relationships predicted an unprecedented, inverse  $\log(\text{TOF})/\eta_{\text{eff}}$  relationship that allowed for simultaneous improvement in both catalysis rates and efficiencies. This approach has yielded the best reported combination of TOF and  $\eta_{\text{eff}}$  for a soluble ORR catalyst.

The ability to combine scaling relationships should be applicable beyond this case study. Optimization by this method, and perhaps even inverse scaling, only requires that the catalytic reaction have at least two properties that affect the  $\text{TOF}_{\text{max}}$  and  $\eta_{\text{eff}}$  in different ways (different slopes). Most molecular electrocatalysis meets this two-descriptor requirement because their mechanisms have pre-equilibrium and rate-limiting steps with different stoichiometries and/or different relationships between the  $k$ ,  $K_{\text{eq}}$ , and the  $\Delta G^\circ$  for each step. ORR catalysis by **1** is a special case of the two-descriptor requirement because a single change to the system—changing the buffer—affects both the catalyst  $E_{1/2}$  and the acid  $\text{p}K_{\text{a}}$ , each of which independently affects the pre-equilibrium and rate-determining steps. Ongoing work in our lab is extending this tandem scaling approach to simultaneous but independent changes in  $E_{1/2}$  and  $\text{p}K_{\text{a}}$ , by changing both the catalyst and the buffer. A similar approach may also be applicable to heterogeneous electrocatalysis, since there is increasing recognition that those mechanisms may also have pre-equilibria and kinetic steps with different properties (19). Therefore, this method of combining scaling relationships may have ramifications for the development of both homogeneous and heterogeneous electrocatalysis of energy-important processes.

## MATERIALS AND METHODS

### Instrumentation

High-resolution mass spectrometry was performed using a Waters Xevo G2-XS QToF mass spectrometer. Ultraviolet-visible (UV-vis) optical spectra were recorded on an Agilent 8452 diode-array spectrometer and were collected using a 1-cm path length cuvette. Infrared (IR) spectrum was recorded on a Bruker Alpha Fourier transform infrared spectrophotometer equipped with an attenuated total reflectance (ATR) attachment. The electrochemical setup is described below. Information about the x-ray diffractometer is described below.

### Materials

2-Nitrobenzaldehyde (Sigma-Aldrich, >95%), tin(II) chloride dihydrate (Sigma-Aldrich, >99%), aqueous hydrochloric acid [Macron, 36 to 38 weight % (wt %)], iron(II) bromide (Sigma-Aldrich, >98%), 2,6-lutidine (Sigma-Aldrich, ReagentPlus, >98%), formaldehyde (Sigma-Aldrich, 37 wt %, containing 10 to 15% methanol as stabilizer), sodium cyanoborohydride (Acros, >98%), methyltrifluoromethylsulfonate (MeOTf; Sigma-Aldrich, >98%), trifluoromethylsulfonic acid (Acros, 99%), neutral aluminum oxide (Sigma-Aldrich, >99%), silica (Sigma-Aldrich, >99%), sodium chloride (Sigma-Aldrich, >99%),

sodium bicarbonate (Sigma-Aldrich, >99%), ammonium hydroxide solution (Sigma-Aldrich, 25 wt %), AcOH (Sigma-Aldrich, >99.9%), BzOH (Sigma-Aldrich, >99.5%), SalOH (Sigma-Aldrich, >99%), TFA (Sigma-Aldrich, ReagentPlus, >99%), tetra-*n*-butylammonium acetate (Sigma-Aldrich, 97%), tetra-*n*-butylammonium benzoate (Sigma-Aldrich, >99%), tetra-*n*-butylammonium salicylate [Tokyo Chemical Industry (TCI), 98%], and sodium trifluoroacetate (Sigma-Aldrich, 98%) were all used as received. All of the solid chemicals were stored in a  $\text{N}_2$  glovebox when not in use.

Tetrahydrofuran, *N,N'*-dimethylformamide (DMF), MeCN, and diethyl ether were all degassed with argon and dried using a Pure Process Technology solvent system before use. Tetra-*n*-butylammonium tetrafluoroborate (Acros, >98%) was stored in a desiccator containing Drierite (calcium sulfate). Bis(cyclopentadienyl)iron(II) (ferrocene or Fc; Sigma-Aldrich, 95%) was recrystallized two times from hexanes before being dried in a  $\text{N}_2$  glovebox. Pyrrole (Acros, 99%) was freshly distilled immediately before each use. The Pur-A-Lyzer Mega Dialysis Kit [Sigma-Aldrich, 1 kDa molecular weight cut-off (MWCO)] was soaked in Milli-Q water for 1 hour before dialysis of **1**. Dioxygen (Airgas, Ultra High Purity) and argon (Airgas, Ultra High Purity) were used as received. *N,N'*-dimethylformamidium triflate ([DMF-H]OTf) and 2,6-lutidinium triflate ([Lut-H]OTf) were synthesized using previously reported methods (20, 21).

### Synthesis of iron $\alpha\beta\alpha\beta$ -tetra(*o*-*N,N',N''*-trimethylanilinium) porphyrin (**1**)

The synthesis of the known iron(III)  $\alpha,\beta,\alpha,\beta$ -5,10,15,20-tetra(ortho-*N,N',N''*-trimethylanilinium)-porphyrin penta(trifluoromethanesulfonate), **1**, was slightly adapted from literature preparation (10). The  $\alpha,\beta,\alpha,\beta$ -5,10,15,20-tetra(ortho-aminophenyl)porphyrin atropisomer was isolated chromatographically using the conditions described in (10). Later in the synthesis, during the final methylation reaction of iron(III)  $\alpha,\beta,\alpha,\beta$ -5,10,15,20-tetra(ortho-*N,N'*-dimethylaminophenyl)porphyrin chloride [chart S1, product **4**, from reference (10)] to the fully quaternized product, 300-equivalent MeOTf were used in place of the reported 100 equivalents. Full quaternization was supported by the high-resolution mass spectrum (HRMS) (which did not reveal any partially quaternized products) and by cyclic voltammetry (see the Supplementary Materials). The product, which was collected in identical yields to the initial report, was purified by dialysis against Milli-Q water (10 ml of sample inside dialyzing bag, 250 ml of surrounding water replaced every 90 min for a total of 12 hours). The product was then recrystallized via slow vapor diffusion of diethyl ether into MeCN containing the iron porphyrin. This recrystallization method yielded crystals suitable for x-ray diffraction (see the Supplementary Materials). HRMS [electron spray ionization (ESI)/quadrupole orthogonal acceleration-time-of-flight] mass/charge ratio ( $m/z$ ): ( $[\text{M}]^{5+} + 4\text{OTf}^-$ ) calculated (calcd) for  $\text{C}_{56}\text{H}_{60}\text{FeN}_8(\text{CF}_3\text{SO}_3)_4$  1496.2373; found 1496.2493. ( $[\text{M}]^{5+} + 3\text{OTf}^-$ ) calcd for  $\text{C}_{56}\text{H}_{60}\text{FeN}_8(\text{CF}_3\text{SO}_3)_3$  673.6426; found 673.6395. UV-vis and IR spectra also agree with what was reported in reference (10), see the Supplementary Materials.

### Electrochemical methods

CV was performed on a CH Instruments model 650D potentiostat. RRDE was conducted using a BASi Epsilon potentiostat and a Pine Instruments rotator (see the Supplementary Materials for further details). CVs used a 3-mm glassy carbon working electrode, a platinum wire counter electrode, and a Ag wire pseudoreference. The

Ag wire pseudoreference was prepared using the method reported by Dempsey *et al.* (22), where a silver wire was sanded and fit snugly into a capillary containing MeCN and 0.1 M [*n*-Bu<sub>4</sub>N][BF<sub>4</sub>]. The solution inside the capillary was separated from bulk solutions using a Vycor tip that had been mechanically sealed to the capillary using heat shrink tubing. The capillary was stored in a solution containing 0.1 M [*n*-Bu<sub>4</sub>N][BF<sub>4</sub>] in-between experiments. For analysis, each voltammogram was internally referenced to ferrocene. The glassy carbon working electrodes were polished after every voltammogram by vigorously polishing on a Buehler felt pad to a mirror-like finish using an alumina slurry (wetted 0.05- $\mu$ m alumina powder). After polishing, the electrode was rinsed with water and MeCN. Internal resistance (iR) compensation was performed before each voltammogram using the CH Instruments integrated software. The typical resistance value was <60 ohm. Considering the typical amount of current passed during catalysis (~200  $\mu$ A), the iR compensation shifted the potential response of <10 mV for most experiments.

All of the buffered electrochemical experiments were performed with a one-to-one buffer of acid and conjugate base. Throughout, we identify the initial buffer concentrations rather than expressly list the acid and conjugate base concentrations. For example, a “10 mM AcOH buffer” means that the solution was prepared to initially contain 10 mM AcOH and 10 mM AcO<sup>-</sup>. These values do not necessarily reflect the concentrations of nonhomoconjugated acid and base (see the Supplementary Materials).

Electrocatalytic, aerobic measurements were performed after sparging the buffered solution and headspace with O<sub>2</sub>. The sparging was performed with pure O<sub>2</sub> at 1 atm unless otherwise noted. To minimize solvent evaporation and accompanying temperature changes, the O<sub>2</sub> was first sparged through an initial bubbler containing pure MeCN. Between each catalytic voltammogram, the working electrode was vigorously polished (see above). To ensure reproducibility, each catalytic voltammogram was also performed in duplicate, and the rates were averaged (see the Supplementary Materials). Unless otherwise specified, every voltammogram reported was collected at 0.1 V/s in a MeCN solution containing 0.1 mM **1** and 0.1 M [*n*-Bu<sub>4</sub>N][BF<sub>4</sub>].

### Single-crystal x-ray diffraction

Crystals of [Fe-*o*-TMA]OTf<sub>5</sub>•2H<sub>2</sub>O (identification code 007b-17062) were grown by slow vapor diffusion of diethyl ether into MeCN on the benchtop. Two water molecules were identified as axial ligands in the solid-state structure. Low-temperature diffraction data ( $\omega$ -scans) were collected on a Rigaku MicroMax-007HF diffractometer coupled to a Saturn994+ charge-coupled device detector with Cu K $\alpha$  ( $\lambda$  = 1.54178 Å) for the structure of [Fe-*o*-TMA]OTf<sub>5</sub>•2H<sub>2</sub>O. The diffraction images were processed and scaled using Rigaku Oxford Diffraction software. The structure was solved with SHELXT and was refined against F<sup>2</sup> on all data by full-matrix least squares with SHELXL (23). The data were refined as an inversion twin. The fractional volume contributions of the second twin component were refined to a value of 0.432(18). All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were included in the model at geometrically calculated positions and refined using a riding model. The isotropic displacement parameters of all hydrogen atoms were fixed 1.2 times the *U* value of the atoms to which they are linked (1.5 times for methyl groups). The Fe-O distance was measured to be 2.101(8) Å, which suggested the assignment as water.

The asymmetric unit of the crystallographic model contains 0.25 of the formula unit C<sub>56</sub>H<sub>64</sub>FeN<sub>8</sub>O<sub>2</sub>•5(CF<sub>3</sub>O<sub>3</sub>S). The iron resides on

the crystallographic  $\bar{4}$  rotation axis at (0,  $\frac{1}{2}$ ,  $\frac{1}{4}$ ). The asymmetric unit also contains a quarter of the porphyrin and 1.25 triflates. One triflate site is on a general position (*x,y,z*), and the other site is near the crystallographic  $\bar{4}$  rotation axis ( $\frac{1}{2}$ ,  $\frac{1}{2}$ ,  $\frac{1}{2}$ ).

The triflate on the general position is disordered over two sites. The thermal ellipsoids for the triflate atoms were restrained to behave as rigid bodies. The site occupancies were fixed at 0.50, and all chemically equivalent 1,2 and 1,3 distances were restrained to be similar. The other triflate was disordered with respect to the  $\bar{4}$  rotation axis. This modeled triflate was placed as a constrained, rigid group based on the difference map (see the Supplementary Materials). The special position constraints were suppressed, and the model occupancy was fixed at 0.25. The program SQUEEZE (24) was used to compensate for the contribution of disordered solvents contained in voids within the crystal lattice from the diffraction intensities. This procedure was applied to the data file, and the submitted model is based on the solvent removed data. On the basis of the total electron density found in the voids (181 e/Å<sup>3</sup>), it is possible that some combination of crystallization solvents is present in the unit cell. See “\_platon\_squeeze\_details” in this .cif for more information.

The full details of the x-ray structure determination (CIF) can be found in the Cambridge Crystallographic Data Center (CCDC), number 1947226 ([Fe-*o*-TMA]OTf<sub>5</sub>•2H<sub>2</sub>O). These data can be obtained free of charge from the CCDC via [www.ccdc.cam.ac.uk/data\\_request/cif](http://www.ccdc.cam.ac.uk/data_request/cif).

### SUPPLEMENTARY MATERIALS

Supplementary material for this article is available at <http://advances.sciencemag.org/cgi/content/full/6/11/eaaz3318/DC1>

Section S1. Spectroscopic characterization of **1**
